The Variation Representation Specification (VRS, pronounced “verse”) is a standard developed by the Global Alliance for Genomic Health to facilitate and improve sharing of genetic information. The Specification consists of a JSON Schema for representing many classes of genetic variation, conventions to maximize the utility of the schema, and a Python implementation that promotes adoption of the standard.

Maximizing the personal, public, research, and clinical value of genomic information will require that clinicians, researchers, and testing laboratories exchange genetic variation data reliably. The Variation Representation Specification (VRS, pronounced “verse”) — written by a partnership among national information resource providers, major public initiatives, and diagnostic testing laboratories — is an open specification to standardize the exchange of variation data.

Here we document the primary contributions of this specification for variation representation:

- **Terminology and information model.** Definitions for biological terms may be abstract or intentionally ambiguous, often accurately reflecting scientific uncertainty or understanding at the time. Abstract and ambiguous terms are not readily translatable into a representation of knowledge. Therefore, the specification begins with precise computational definitions for biological concepts that are essential to representing sequence variation. The VRS information model specifies how the computational definitions are to be represented in fields, semantics, objects, and object relationships.
- **Machine readable schema.** To be useful for information exchange, the information model should be realized in a schema definition language. The VRS schema is currently implemented using JSON Schema, however it is intended to support translations to other schema systems (e.g. XML, OpenAPI, and GraphQL). The schema repository includes language-agnostic tests for ensuring schema compliance in downstream implementations.
- **Conventions that promote reliable data sharing.** VRS recommends conventions regarding the use of the schema and that facilitate data sharing. For example, VRS recommends using fully justified allele normalization using an algorithm inspired by NCBI’s SPDI project.
- **Globally unique computed identifiers.** This specification also recommends a specific algorithm for constructing distributed and globally-unique identifiers for molecular variation. Importantly, this algorithm enables data providers and consumers to computationally generate consistent, globally unique identifiers for variation without a central authority.
- **A Python implementation.** We provide a Python package (`vr-python`) that demonstrates the above schema and algorithms, and supports translation of existing variant representation schemes into VRS for use in genomic data sharing. It may be used as the basis for development in Python, but it is not required in order to use VRS.

The machine readable schema definitions and example code are available online at the VRS repository (<https://github.com/ga4gh/vr-spec>).

Readers may wish to view a *complete example* before reading the specification.

For a discussion of VRS with respect to existing standards, such as HGVS, SPDI, and VCF, see *Relationship of VRS to existing standards*.

Terminology & Information Model

When biologists define terms in order to describe phenomena and observations, they rely on a background of human experience and intelligence for interpretation. Definitions may be abstract, perhaps correctly reflecting uncertainty of our understanding at the time. Unfortunately, such terms are not readily translatable into an unambiguous representation of knowledge.

For example, “allele” might refer to “an alternative form of a gene or locus” [Wikipedia], “one of two or more forms of the DNA sequence of a particular gene” [ISOGG], or “one of a set of coexisting sequence alleles of a gene” [Sequence Ontology]. Even for human interpretation, these definitions are inconsistent: does the definition precisely describe a specific change on a specific sequence, or, rather, a more general change on an undefined sequence? In addition, all three definitions are inconsistent with the practical need for a way to describe sequence changes outside regions associated with genes.

The computational representation of biological concepts requires translating precise biological definitions into data structures that can be used by implementers. This translation should result in a representation of information that is consistent with conventional biological understanding and, ideally, be able to accommodate future data as well. The resulting *computational representation* of information should also be cognizant of computational performance, the minimization of opportunities for misunderstanding, and ease of manipulating and transforming data.

Accordingly, for each term we define below, we begin by describing the term as used by biologists (**biological definition**) as available. When a term has multiple biological definitions, we explicitly choose one of them for the purposes of this specification. We then provide a computer modelling definition (**computational definition**) that reformulates the biological definition in terms of information content. We then translate each of these computational definitions into precise specifications for the (**logical model**). Terms are ordered “bottom-up” so that definitions depend only on previously-defined terms.

Note: The keywords “MUST”, “MUST NOT”, “REQUIRED”, “SHALL”, “SHALL NOT”, “SHOULD”, “SHOULD NOT”, “RECOMMENDED”, “MAY”, and “OPTIONAL” in this document are to be interpreted as described in RFC 2119.

2.1 Data Model Notes and Principles

- VRS uses `snake_case` to represent compound words. Although the schema is currently JSON-based (which would typically use camelCase), VRS itself is intended to be neutral with respect to languages and database.
- VRS objects are *value objects*. Two objects are considered equal if and only if their respective attributes are equal. As value objects, VRS objects are used as primitive types and SHOULD NOT be used as containers for related data. Instead, related data should be associated with VRS objects through identifiers. See *Computed Identifiers*.
- Error handling is intentionally unspecified and delegated to implementation. VRS provides foundational data types that enable significant flexibility. Except where required by this specification, implementations may choose whether and how to validate data. For example, implementations MAY choose to validate that particular combinations of objects are compatible, but such validation is not required.
- We recognize that a common desire may be to have human-readable identifiers associated with VRS objects. We recommend using the `_id` field (see *Optional Attributes* below) to create a lookup for any such identifiers (see *example usage*), and provide reference methods for creating VRS identifiers from other common variant formats (see the *HGVS translation example*).

2.2 Optional Attributes

- VRS attributes use a leading underscore to represent optional attributes that are not part of the value object. Such attributes are not considered when evaluating equality or creating computed identifiers. Currently, the only such attribute in the specification is the `_id` attribute.
- The `_id` attribute is available to identifiable objects, and MAY be used by an implementation to store the identifier for a VRS object. If used, the stored `_id` element MUST be a *CURIE*. If used for creating a *Truncated Digest* (*sha512t24u*) for parent objects, the stored element must be a *GA4GH Computed Identifier*.

2.3 Primitive Concepts

2.3.1 CURIE

Biological Definition

None.

Computational Definition

A *CURIE* formatted string. A CURIE string has the structure `prefix:reference` (W3C Terminology).

Implementation Guidance

- All identifiers in VRS MUST be a valid *Compact URI (CURIE)*, regardless of whether the identifier refers to GA4GH VRS objects or external data.
- For GA4GH VRS objects, this specification RECOMMENDS using globally unique *Computed Identifiers* for use within *and* between systems.
- For external data, CURIE-formatted identifiers MUST be used. When an appropriate namespace exists at `identifiers.org`, that namespace MUST be used. When an appropriate namespace does not exist at `identifiers.org`, support is implementation-dependent. That is, implementations MAY choose whether and how to support informal or local namespaces.

- Implementations **MUST** use CURIE identifiers verbatim. Implementations **MAY NOT** modify CURIEs in any way (e.g., case-folding).

Examples

Identifiers for GRCh38 chromosome 19:

```
ga4gh:SQ.IIB53T8CNeJJdUqzn9V_JnRtQadwWCb1
refseq:NC_000019.10
grch38:19
```

See *Identifier Construction* for examples of CURIE-based identifiers for VRS objects.

2.3.2 Residue

Biological Definition

A residue refers to a specific [monomer](#) within the [polymeric chain](#) of a [protein](#) or [nucleic acid](#) (Source: [Wikipedia Residue page](#)).

Computational Definition

A character representing a specific residue (i.e., molecular species) or groupings of these (“ambiguity codes”), using [one-letter IUPAC abbreviations](#) for nucleic acids and amino acids.

2.3.3 Sequence

Biological Definition

A contiguous, linear polymer of nucleic acid or amino acid residues.

Computational Definition

A character string of [Residues](#) that represents a biological sequence using the conventional sequence order (5'-to-3' for nucleic acid sequences, and amino-to-carboxyl for amino acid sequences). IUPAC ambiguity codes are permitted in Sequences.

Information Model

A Sequence is a string, constrained to contain only characters representing IUPAC nucleic acid or amino acid codes.

Implementation Guidance

- Sequences **MAY** be empty (zero-length) strings. Empty sequences are used as the replacement Sequence for deletion Alleles.
- Sequences **MUST** consist of only uppercase IUPAC abbreviations, including ambiguity codes.
- A Sequence provides a stable coordinate system by which an *Allele* **MAY** be located and interpreted.
- A Sequence **MAY** have several roles. A “reference sequence” is any Sequence used to define an *Allele*. A Sequence that replaces another Sequence is called a “replacement sequence”.
- In some contexts outside VRS, “reference sequence” may refer to a member of set of sequences that comprise a genome assembly. In the VRS specification, any sequence may be a “reference sequence”, including those in a genome assembly.
- For the purposes of representing sequence variation, it is not necessary that Sequences be explicitly “typed” (i.e., DNA, RNA, or AA).

2.4 Non-variation classes

2.4.1 SequenceInterval (Abstract Class)

Biological Definition

None.

Computational Definition

The *SequenceInterval* abstract class defines a range on a *Sequence*, possibly with length zero, and specified using *Interbase Coordinates*. An Interval MAY be a *SimpleInterval* with a single start and end coordinate. *Future Location and SequenceInterval types* will enable other methods for describing where *Variation* occurs. Any of these MAY be used as the SequenceInterval for Location.

VRS Uses Interbase Coordinates

GA4GH VRS uses interbase coordinates when referring to spans of sequence.

Interbase coordinates refer to the zero-width points before and after *residues*. An interval of interbase coordinates permits referring to any span, including an empty span, before, within, or after a sequence. See *Interbase Coordinates* for more details on this design choice. Interbase coordinates are always zero-based.

SimpleInterval

Computational Definition

A *SequenceInterval (Abstract Class)* with a single start and end coordinate.

Information Model

Field	Type	Limits	Description
type	string	1..1	MUST be “SimpleInterval”
start	uint64	1..1	start position
end	uint64	1..1	end position

Implementation Guidance

- Implementations MUST enforce values $0 \leq \text{start} \leq \text{end}$. In the case of double-stranded DNA, this constraint holds even when a feature is on the complementary strand.
- VRS uses Interbase coordinates because they provide conceptual consistency that is not possible with residue-based systems (see *rationale*). Implementations will need to convert between interbase and 1-based inclusive residue coordinates familiar to most human users.
- Interbase coordinates start at 0 (zero).
- The length of an interval is $\text{end} - \text{start}$.
- An interval in which $\text{start} == \text{end}$ is a zero width point between two residues.
- An interval of length $== 1$ MAY be colloquially referred to as a position.
- Two intervals are *equal* if the their start and end coordinates are equal.
- Two intervals *intersect* if the start or end coordinate of one is strictly between the start and end coordinates of the other. That is, if:

- $b.start < a.start < b.end$ OR
 - $b.start < a.end < b.end$ OR
 - $a.start < b.start < a.end$ OR
 - $a.start < b.end < a.end$
- Two intervals a and b *coincide* if they intersect or if they are equal (the equality condition is REQUIRED to handle the case of two identical zero-width SimpleIntervals).
 - $\langle start, end \rangle = \langle 0, 0 \rangle$ refers to the point with width zero before the first residue.
 - $\langle start, end \rangle = \langle i, i+1 \rangle$ refers to the $i+1$ th (1-based) residue.
 - $\langle start, end \rangle = \langle N, N \rangle$ refers to the position after the last residue for Sequence of length N .
 - See example notebooks in [GA4GH VR Python Implementation](#).

Examples

```
{
  "end": 44908822,
  "start": 44908821,
  "type": "SimpleInterval"
}
```

2.4.2 CytobandInterval

Computational Definition

A contiguous region specified by chromosomal bands features.

Information Model

Field	Type	Limits	Description
type	string	1..1	MUST be "CytobandInterval"
start	string	1..1	name of feature start
end	string	1..1	name of feature end

Implementation Guidance

- *start* and *end* attributes of CytobandInterval are intentionally specified vaguely in order to accommodate a wide variety of uses. Examples include named markers on chromosomes, cytogenetic bands, and legacy marker names found in older scientific literature.
- When *CytobandInterval* refers to cytogenetic bands, the valid values for, and the syntactic structure of, the *start* and *end* depend on the species. When using *CytobandInterval* to refer to human cytogenetic bands, ISCN conventions MUST be used. Bands are denoted by the arm ("p" or "q") and position (e.g., "22", "22.3", or the symbolic values "cen" or "ter"). If *start* and *end* are on different arms, they SHOULD correspond to the p-arm and q-arm locations respectively. If *start* and *end* are on the same arm, *start* MUST be the more centromeric position (i.e., with lower band and sub-band numbers).

Examples

```
{
  "end": "q22.3",
  "start": "q22.2",
  "type": "CytobandInterval"
}
```

2.4.3 Location (Abstract Class)

Biological Definition

As used by biologists, the precision of “location” (or “locus”) varies widely, ranging from precise start and end numerical coordinates defining a Location, to bounded regions of a sequence, to conceptual references to named genomic features (e.g., chromosomal bands, genes, exons) as proxies for the Locations on an implied reference sequence.

Computational Definition

The *Location* abstract class refers to position of a contiguous segment of a biological sequence. The most common and concrete Location is a *SequenceLocation*, i.e., a Location based on a named sequence and an Interval on that sequence. Additional *Intervals and Locations* may also be conceptual or symbolic locations, such as a cytoband region or a gene. Any of these may be used as the Location for Variation.

Implementation Guidance

- Location refers to a position. Although it MAY imply a sequence, the two concepts are not interchangeable, especially when the location is non-specific (e.g., a range) or symbolic (a gene).

ChromosomeLocation

Biological Definition

Chromosomal locations based on named features.

Computational Definition

A ChromosomeLocation is a *Location (Abstract Class)* that is defined by a named chromosomal features.

Information Model

Field	Type	Limits	Description
<code>_id</code>	<i>CURIE</i>	0..1	Location id; MUST be unique within document
<code>type</code>	string	1..1	MUST be “ChromosomeLocation”
<code>species</code>	<i>CURIE</i>	1..1	An external reference to a species taxonomy. Default: “taxonomy:9606” (Human). See Implementation Guidance, below.
<code>chr</code>	string	1..1	The symbolic chromosome name
<code>interval</code>	<i>Cytoband-Interval</i>	1..1	The chromosome region based on feature names

Implementation Guidance

- ChromosomeLocation is intended to enable the representation of cytogenetic results from karyotyping or low-resolution molecular methods, particularly those found in older scientific literature. Precise *SequenceLocation* should be preferred when nucleotide-scale location is known.
- *species* is specified using the NCBI taxonomy. The CURIE prefix MUST be “taxonomy”, corresponding to the NCBI taxonomy prefix at identifiers.org, and the CURIE reference MUST be an NCBI taxonomy identifier (e.g., 9606 for Homo sapiens).
- ChromosomeLocation is intended primarily for Humans. Support for other species is possible and will be considered based on community feedback.
- *chromosome* is an archetypal chromosome name. Valid values for, and the syntactic structure of, *chromosome* depends on the species. *chromosome* MUST be an official sequence name from NCBI Assembly. For Humans, valid chromosome names are 1..22, X, Y (case-sensitive).

- *interval* refers to a contiguous region specified named markers, which are presumed to exist on the specified chromosome. See *CytobandInterval* for additional information.
- The conversion of *ChromosomeLocation* instances to *SequenceLocation* instances is out-of-scope for VRS. When converting *start* and *end* to *SequenceLocations*, the positions MUST be interpreted as inclusive ranges that cover the maximal extent of the region.
- Data for converting cytogenetic bands to precise sequence coordinates are available at [NCBI GDP](#), [UCSC GRCh37 \(hg19\)](#), [UCSC GRCh38 \(hg38\)](#), and [bioutils \(Python\)](#).
- See also the rationale for *Not using External Chromosome Declarations*.

Examples

```
{
  "chr": "11",
  "interval": {
    "end": "q22.3",
    "start": "q22.2",
    "type": "CytobandInterval"
  },
  "species_id": "taxonomy:9606",
  "type": "ChromosomeLocation"
}
```

SequenceLocation

Biological Definition

A specified subsequence within another sequence that is used as a reference sequence.

Computational Definition

A Location subclass for describing a defined *SequenceInterval* (*Abstract Class*) on a named *Sequence*.

Information Model

Field	Type	Limits	Description
<code>_id</code>	<i>CURIE</i>	0..1	Location id; MUST be unique within document
<code>type</code>	string	1..1	MUST be “SequenceLocation”
<code>sequence_id</code>	<i>CURIE</i>	1..1	An id mapping to the <i>Computed Identifiers</i> of the external database Sequence containing the sequence to be located.
<code>interval</code>	<i>SequenceInterval</i> (<i>Abstract Class</i>)	1..1	Position of feature on reference sequence specified by <code>sequence_id</code> .

Implementation Guidance

- For a *Sequence* of length *n*:
 - 0 *interval.start interval.end n*
 - interbase coordinate 0 refers to the point before the start of the Sequence
 - interbase coordinate *n* refers to the point after the end of the Sequence.
- Coordinates MUST refer to a valid Sequence. VRS does not support referring to intronic positions within a transcript sequence, extrapolations beyond the ends of sequences, or other implied sequence.

Important: HGVS permits variants that refer to non-existent sequence. Examples include coordinates extrapolated beyond the bounds of a transcript and intronic sequence. Such variants are not representable using VRS and MUST be projected to a genomic reference in order to be represented.

Examples

```
{
  "interval": {
    "end": 44908822,
    "start": 44908821,
    "type": "SimpleInterval"
  },
  "sequence_id": "ga4gh:SQ.IIB53T8CNeJJdUqzn9V_JnRtQadwWCbl",
  "type": "SequenceLocation"
}
```

2.4.4 State (Abstract Class)

Biological Definition

None.

Computational Definition

State objects are one of two primary components specifying a VRS *Allele* (in addition to *Location (Abstract Class)*), and the designated components for representing change (or non-change) of the features indicated by the Allele Location. As an abstract class, *State* currently encompasses single and contiguous *Sequence* changes (see *SequenceState*), with additional types under consideration (see *State Classes*).

SequenceState

Biological Definition

None.

Computational Definition

The *SequenceState* class specifically captures a *Sequence* as a *State (Abstract Class)*. This is the *State* class to use for representing “ref-alt” style variation, including SNVs, MNVs, del, ins, and delins.

Information Model

Field	Type	Limits	Description
type	string	1..1	MUST be “SequenceState”
sequence	string	1..1	The string of sequence residues that is to be used as the state for other types.

Examples

```
{
  "sequence": "T",
  "type": "SequenceState"
}
```

2.5 Variation

The Variation class is the conceptual root of all types of variation, both current and future.

Biological Definition

In biology, variation is often used to mean *sequence* variation, describing the differences observed in DNA or AA bases among individuals.

Computational Definition

The *Variation* abstract class is the top-level object in the *Current Variation Representation Specification Schema* and represents the concept of a molecular state. The representation and types of molecular states are widely varied, and there are several *Variation Classes* currently under consideration to capture this diversity. The primary Variation subclass defined by the VRS 1.1 specification is the *Allele*, with the *Text* subclass for capturing other Variations that are not yet covered.

2.5.1 Allele

Biological Definition

One of a number of alternative forms of the same gene or same genetic locus. In the context of biological sequences, “allele” refers to one of a set of specific changes within a *Sequence*. In the context of VRS, Allele refers to a Sequence or Sequence change with respect to a reference sequence, without regard to genes or other features.

Computational Definition

An Allele is an assertion of the *State* of a biological sequence at a *Location*.

Information Model

Field	Type	Limits	Description
_id	<i>CURIE</i>	0..1	Variation Id; MUST be unique within document
type	string	1..1	MUST be “Allele”
location	<i>Location (Abstract Class) CURIE</i>	1..1	Where Allele is located
state	<i>State (Abstract Class)</i>	1..1	State at location

Implementation Guidance

- The *State* and *Location* subclasses respectively represent diverse kinds of sequence changes and mechanisms for describing the locations of those changes, including varying levels of precision of sequence location and categories of sequence changes.
- Implementations MUST enforce values `interval.end` `sequence_length` when the Sequence length is known.
- Alleles are equal only if the component fields are equal: at the same location and with the same state.
- Alleles MAY have multiple related representations on the same Sequence type due to normalization differences.
- Implementations SHOULD normalize Alleles using “*justified*” *normalization* whenever possible to facilitate comparisons of variation in regions of representational ambiguity.
- Implementations MUST normalize Alleles using “*justified*” *normalization* when generating a *Computed Identifiers*.
- When the alternate Sequence is the same length as the interval, the lengths of the reference Sequence and imputed Sequence are the same. (Here, imputed sequence means the sequence derived by applying the Allele to the reference sequence.) When the replacement Sequence is shorter than the length of the interval, the

imputed Sequence is shorter than the reference Sequence, and conversely for replacements that are larger than the interval.

- When the replacement is "" (the empty string), the Allele refers to a deletion at this location.
- The Allele entity is based on Sequence and is intended to be used for intragenic and extragenic variation. Alleles are not explicitly associated with genes or other features.
- Biologically, referring to Alleles is typically meaningful only in the context of empirical alternatives. For modelling purposes, Alleles MAY exist as a result of biological observation or computational simulation, i.e., virtual Alleles.
- “Single, contiguous” refers the representation of the Allele, not the biological mechanism by which it was created. For instance, two non-adjacent single residue Alleles could be represented by a single contiguous multi-residue Allele.
- The terms “allele” and “variant” are often used interchangeably, although this use may mask subtle distinctions made by some users.
 - In the genetics community, “allele” may also refer to a haplotype.
 - “Allele” connotes a state whereas “variant” connotes a change between states. This distinction makes it awkward to use variant to refer to the concept of an unchanged position in a Sequence and was one of the factors that influenced the preference of “Allele” over “Variant” as the primary subject of annotations.
 - See *Use “Allele” rather than “Variant”* for further details.
- When a trait has a known genetic basis, it is typically represented computationally as an association with an Allele.
- This specification’s definition of Allele applies to all Sequence types (DNA, RNA, AA).

Examples

```
{
  "location": {
    "interval": {
      "end": 44908822,
      "start": 44908821,
      "type": "SimpleInterval"
    },
    "sequence_id": "ga4gh:SQ.IIB53T8CNeJJdUqzn9V_JnRtQadwWCbl",
    "type": "SequenceLocation"
  },
  "state": {
    "sequence": "T",
    "type": "SequenceState"
  },
  "type": "Allele"
}
```

2.5.2 Text

Biological Definition

None

Computational Definition

The *Text* subclass of *Variation* is intended to capture textual descriptions of variation that cannot be parsed by other *Variation* subclasses, but are still treated as variation.

Information Model

Field	Type	Limits	Description
<code>_id</code>	<i>CURIE</i>	0..1	Variation Id; MUST be unique within document
<code>type</code>	string	1..1	MUST be "Text"
<code>definition</code>	string	1..1	The textual variation representation not parsable by other subclasses of Variation.

Implementation Guidance

- An implementation MUST represent Variation with subclasses other than Text if possible.
- An implementation SHOULD define or adopt conventions for defining the strings stored in Text.definition.
- If a future version of VRS is adopted by an implementation and the new version enables defining existing Text objects under a different Variation subclass, the implementation MUST construct a new object under the other Variation subclass. In such a case, an implementation SHOULD persist the original Text object and respond to queries matching the Text object with the new object.
- Additional Variation subclasses are continually under consideration. Please open a [GitHub issue](#) if you would like to propose a Variation subclass to cover a needed variation representation.

Examples

```
{
  "definition": "APOE loss",
  "type": "Text"
}
```

2.5.3 Haplotype

Biological Definition

A specific combination of Alleles that occur together on single sequence in one or more individuals.

Computational Definition

A specific combination of non-overlapping Alleles that co-occur on the same reference sequence.

Information Model

Field	Type	Limits	Description
<code>_id</code>	<i>CURIE</i>	0..1	Variation Id; MUST be unique within document
<code>type</code>	string	1..1	MUST be "Haplotype"
<code>members</code>	<i>Allele</i> [] <i>CURIE</i> []	1..*	List of Alleles, or references to Alleles, that comprise this Haplotype

Implementation Guidance

- Haplotypes are an assertion of Alleles known to occur "in cis" or "in phase" with each other.
- All Alleles in a Haplotype MUST be defined on the same reference sequence.
- Alleles within a Haplotype MUST not overlap ("overlap" is defined in Interval).
- The locations of Alleles within the Haplotype MUST be interpreted independently. Alleles that create a net insertion or deletion of sequence MUST NOT change the location of "downstream" Alleles.
- The *members* attribute is required and MUST contain at least one Allele.

Sources

- **ISOGG: Haplotype** — A haplotype is a combination of alleles (DNA sequences) at different places (loci) on the chromosome that are transmitted together. A haplotype may be one locus, several loci, or an entire chromosome depending on the number of recombination events that have occurred between a given set of loci.
- **SO: haplotype (SO:0001024)** — A haplotype is one of a set of coexisting sequence variants of a haplotype block.
- **GENO: Haplotype (GENO:0000871)** - A set of two or more sequence alterations on the same chromosomal strand that tend to be transmitted together.

Examples

An APOE-ε1 Haplotype with inline Alleles:

```
{
  "members": [
    {
      "location": {
        "interval": {
          "end": 44908684,
          "start": 44908683,
          "type": "SimpleInterval"
        },
        "sequence_id": "ga4gh:SQ.IIB53T8CNeJJdUqzn9V_JnRtQadwWCbl",
        "type": "SequenceLocation"
      },
      "state": {
        "sequence": "C",
        "type": "SequenceState"
      },
      "type": "Allele"
    },
    {
      "location": {
        "interval": {
          "end": 44908822,
          "start": 44908821,
          "type": "SimpleInterval"
        },
        "sequence_id": "ga4gh:SQ.IIB53T8CNeJJdUqzn9V_JnRtQadwWCbl",
        "type": "SequenceLocation"
      },
      "state": {
        "sequence": "T",
        "type": "SequenceState"
      },
      "type": "Allele"
    }
  ],
  "type": "Haplotype"
}
```

The same APOE-ε1 Haplotype with referenced Alleles:

```
{
  "members": [
    "ga4gh:VA.iXjilHZiyCEoD3wVMPMXG3B8BtYfL88H",
  ]
}
```

(continues on next page)

(continued from previous page)

```

    "ga4gh:VA.EgHPXXhULTwoP4-ACfs-YCXaeUQJBjH_"
  ],
  "type": "Haplotype"
}

```

The GA4GH computed identifier for these Haplotypes is *ga4gh:VH.NAVnEuaP9gf41OxnPM56XxWQfdFNcUxJ*, regardless of the whether the Variation objects are inlined or referenced, and regardless of order. See *Computed Identifiers* for more information.

2.5.4 VariationSet

Biological Definition

Sets of variation are used widely, such as sets of variants in dbSNP or ClinVar that might be related by function.

Computational Definition

An unconstrained set of Variation objects or references.

Information Model

Field	Type	Lim-its	Description
<code>_id</code>	<i>CURIE</i>	0..1	Identifier of the VariationSet.
<code>type</code>	string	1..1	MUST be "VariationSet"
<code>members</code>	<i>Variation</i> [] or <i>CURIE</i> []	0..*	List of Variation objects or identifiers. Attribute is required, but MAY be empty.

Implementation Guidance

- The VariationSet identifier MAY be computed as described in *Computed Identifiers*, in which case the identifier effectively refers to a static set because a different set of members would generate a different identifier.
- *members* may be specified as Variation objects or CURIE identifiers.
- CURIEs MAY refer to entities outside the *ga4gh* namespace. However, objects that use non-*ga4gh* identifiers MAY NOT use the *Computed Identifiers* mechanism.
- VariationSet identifiers computed using the GA4GH *Computed Identifiers* process do *not* depend on whether the Variation objects are inlined or referenced, and do *not* depend on the order of members.
- Elements of *members* must be subclasses of Variation, which permits sets to be nested.
- Recursive sets are not meaningful and are not supported.
- VariationSets may be empty.

Examples

Inlined Variation objects:

```

{
  "members": [
    {
      "location": {
        "interval": {
          "end": 11,
          "start": 10,

```

(continues on next page)

(continued from previous page)

```

      "type": "SimpleInterval"
    },
    "sequence_id": "ga4gh:SQ.01234abcde",
    "type": "SequenceLocation"
  },
  "state": {
    "sequence": "C",
    "type": "SequenceState"
  },
  "type": "Allele"
},
{
  "location": {
    "interval": {
      "end": 21,
      "start": 20,
      "type": "SimpleInterval"
    },
    "sequence_id": "ga4gh:SQ.01234abcde",
    "type": "SequenceLocation"
  },
  "state": {
    "sequence": "C",
    "type": "SequenceState"
  },
  "type": "Allele"
},
{
  "location": {
    "interval": {
      "end": 31,
      "start": 30,
      "type": "SimpleInterval"
    },
    "sequence_id": "ga4gh:SQ.01234abcde",
    "type": "SequenceLocation"
  },
  "state": {
    "sequence": "C",
    "type": "SequenceState"
  },
  "type": "Allele"
}
],
"type": "VariationSet"
}

```

Referenced Variation objects:

```

{
  "members": [
    "ga4gh:VA.6xjh0Ikz88s7MhcyN5GJTalp712-M10W",
    "ga4gh:VA.7k2lyIsIsoBgRFP1fnIOeCeEgj_2B07F",
    "ga4gh:VA.ikcK330gH3bYO2sw9QcTsoptTFnk_Xjh"
  ],
  "type": "VariationSet"
}

```

The GA4GH computed identifier for these sets is *ga4gh:VS.WVC_R7OJ688EQX3NrgpJfsf_ctQUsVP3*, regardless of the whether the Variation objects are inlined or referenced, and regardless of order. See *Computed Identifiers* for more information.

3.1 Overview

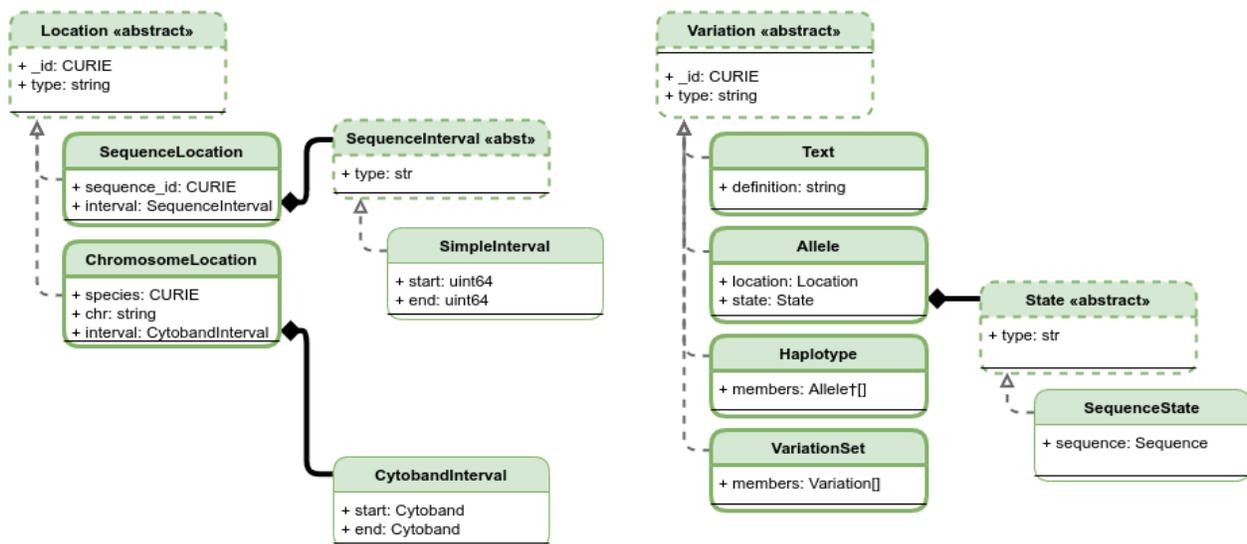

Fig. 1: Current Variation Representation Specification Schema

Legend Classes (data types) are shown as boxes. Abstract classes are denoted by dotted outline; “identifiable” classes, which may be referenced with an identifier, are denoted by bold borders; non-identifiable classes are denoted by thin solid borders. Inheritance and composition are shown with dotted gray and solid black lines connecting classes, respectively. All classes have a string *type*. Abstract classes enable specializations of concepts in this and future versions of VRS. Identifiable classes have an optional *_id* attribute. Non-identifiable classes exist only to structure data always occur “inline” within objects. Inherited attributes are not shown in this diagram. An asterisk (*) denotes a nullable attribute. A dagger (†) denotes attributes that may be specified with inline objects or references to the same type.

[source]

3.2 Machine Readable Specifications

The machine readable VRS Specification is written using [JSON Schema](#).

The schema itself is written in `YAML` (`vr.yaml`) and converted to `JSON` (`vr.json`).

Contributions to the schema **MUST** be written in the `YAML` document.

Implementation Guide

This section describes the data and algorithmic components that are REQUIRED for implementations of VRS.

- *Required External Data*: All implementations will require access to sequences and sequence accessions. The Required External Data section provides guidance on the abstract functionality that is required in order to implement VR.
- *Normalization*: Expands Alleles to the maximal region of representational ambiguity.
- *Computed Identifiers*: Generate globally unique identifiers based solely on the variation definition.

4.1 Required External Data

All VRS implementations will require external data regarding sequences and sequence metadata. The choices of data sources and access methods are left to implementations. This section provides guidance about how to implement required data and helps implementers estimate effort. This section is descriptive only: it is not intended to impose requirements on interface to, or sources of, external data. For clarity and completeness, this section also describes the contexts in which external data are used.

4.1.1 Contexts

- **Conversion from other variant formats** When converting from other variation formats, implementations **MUST** translate primary database accessions or identifiers (e.g., `NM_000551.3` or `refseq:NM_000551.3`) to a GA4GH VRS sequence identifier (`ga4gh:SQ.v_QTc1p-MUYdgrRv4LMT6ByXIOsdw3C_`)
- **Conversion to other variant formats** When converting to other variation formats, implementations **SHOULD** translate GA4GH VR sequence identifier (`ga4gh:SQ.v_QTc1p-MUYdgrRv4LMT6ByXIOsdw3C_`) to primary database identifiers (`refseq:NM_000551.3`) that will be more readily recognized by users.
- **Normalization** During *Normalization*, implementations will need access to sequence length and sequence contexts.

4.1.2 Data Services

The following tables summarizes data required in the above contexts:

Table 1: Data Service Descriptions

Data Service	Description	Contexts
sequence	For a given sequence identifier and range, return the corresponding sub-sequence.	normalization
sequence length	For a given sequence identifier, return the length of the sequence	normalization
identifier translation	For a given sequence identifier and target namespace, return all identifiers in the target namespace that are equivalent to the given identifier.	Conversion to/from other formats

Note: Construction of the GA4GH computed identifier for a sequence is described in *Computed Identifiers*.

4.1.3 Suggested Implementation

In order to maximize portability and to insulate implementations from decisions about external data sources, implementers should consider writing an abstract data proxy interface that to define a service, and then implement this interface for each data backend to be supported. The *vr-python: GA4GH VRS Python Implementation DataProxy* class provides an example of this design pattern and sample replies.

The DataProxy interface defines three methods:

- `get_sequence(identifier, start, end)`: Given a sequence identifier and start and end coordinates, return the corresponding sequence segment.
- `get_metadata(identifier)`: Given a sequence identifier, return a dictionary of length, alphabet, and known aliases.
- `translate_sequence_identifier(identifier, namespace)`: Given a sequence identifier, return all aliases in the specified namespace. Zero or more aliases may be returned.

GA4GH VR Python Implementation implements the DataProxy interface using a local `SeqRepo` instance backend and using a `SeqRepo REST Service` backend. A GA4GH refget implementation has been started, but is pending interface changes to support lookup using primary database accessions.

Examples

The following examples are taken from *VR Python Notebooks*:

```
from ga4gh.vr.dataproxy import SeqRepoRESTDataProxy
seqrepo_rest_service_url = "http://localhost:5000/seqrepo"
dp = SeqRepoRESTDataProxy(base_url=seqrepo_rest_service_url)

def get_sequence(identifier, start=None, end=None):
    """returns sequence for given identifier, optionally limited
    to interbase <start, end> interval"""
    return dp.get_sequence(identifier, start, end)
def get_sequence_length(identifier):
```

(continues on next page)

(continued from previous page)

```

    """return length of given sequence identifier"""
    return dp.get_metadata(identifier)["length"]
def translate_sequence_identifier(identifier, namespace):
    """return for given identifier, return *list* of equivalent identifiers in given_
    ↪ namespace"""
    return dp.translate_sequence_identifier(identifier, namespace)

```

```

get_sequence_length("ga4gh:SQ.IIB53T8CNeJJdUqzn9V_JnRtQadwWCbl")
58617616

```

```

start, end = 44908821-25, 44908822+25
get_sequence("ga4gh:SQ.IIB53T8CNeJJdUqzn9V_JnRtQadwWCbl", start, end)
'CCGCGATGCCGATGACCTGCAGAAGCGCCTGGCAGTGTACCAGGCCGGGGC'

```

```

translate_sequence_identifier("GRCh38:19", "ga4gh")
['ga4gh:SQ.IIB53T8CNeJJdUqzn9V_JnRtQadwWCbl']

```

```

translate_sequence_identifier("ga4gh:SQ.IIB53T8CNeJJdUqzn9V_JnRtQadwWCbl", "GRCh38")
['GRCh38:19', 'GRCh38:chr19']

```

4.2 Normalization

In VRS, “normalization” refers to the process of rewriting an ambiguous variation representation of variation into a canonical form. Normalization eliminates a class of ambiguity that impedes comparison of variation across systems.

In the sequencing community, “normalization” refers to the process of converting a given sequence variant into a canonical form, typically by left- or right-shuffling insertion/deletion variants. VRS normalization extends this concept to all classes of VRS Variation objects.

Implementations **MUST** provide a `normalize` function that accepts *any* Variation object and returns a normalized Variation. Guidelines for these functions are below.

4.2.1 General Normalization Rules

- Object types that do not have explicit VRS normalization rules below are returned as-is. That is, all types of Variation **MUST** be supported, even if such objects are unchanged.
- VRS normalization functions are idempotent: Normalizing a previously-normalized object returns an equivalent object.
- VRS normalization functions are not necessarily homomorphic: That is, the input and output objects may be of different types.

4.2.2 Allele Normalization

Certain insertion or deletion alleles may have ambiguous representations when using conventional sequence normalization, resulting in significant challenges when comparing such alleles.

VRS uses a “fully-justified” normalization algorithm inspired by NCBI’s Variant Overprecision Correction Algorithm¹. Fully-justified normalization expands such ambiguous representation over the entire region of ambiguity, resulting in an *unambiguous* representation that may be readily compared with other alleles.

VRS RECOMMENDS that Alleles at precise locations are normalized to a fully justified form unless there is a compelling reason to do otherwise. Alleles SHOULD be normalized in order to generate *Computed Identifiers*.

The process for fully justifying an Allele is outlined below.

0. Given an Allele:
 - a. Let *reference allele sequence* refer to the subsequence at the Allele’s SequenceLocation.
 - b. Let *alternate allele sequence* be the sequence in the Allele’s State object.
 - c. Let *start* and *end* initially be the *start* and *end* of the Allele’s SequenceLocation.
1. Trim sequences:
 - a. Remove suffixes common to the *reference allele sequence* and *alternate allele sequence*, if any. Decrement *end* by the length of the trimmed suffix.
 - b. Remove prefixes common to the *reference allele sequence* and *alternate allele sequence*, if any. Increment *start* by the length of the trimmed prefix.
2. If *reference allele sequence* and *alternate allele sequence* are empty, the input Allele is a reference Allele. Return the input Allele unmodified.
3. If *reference allele sequence* and *alternate allele sequence* are non-empty, the input Allele has been reduced to a substitution Allele. Construct and return a new Allele with the current *start*, *end*, and *alternate allele sequence*.

NOTE: The remaining cases are that exactly one of *reference allele sequence* or *alternate allele sequence* is empty. If *reference allele sequence* is empty, the Allele represents an insertion in the reference. If *alternate allele sequence* is empty, the Allele represents a deletion in the reference.
4. Determine bounds of ambiguity:
 - a. Left roll: While the terminal base of all non-empty alleles is equal to the base *prior* to the current position, circularly permute all alleles *rightward* and move the current position *leftward*. When terminating, return *left_roll*, the number of steps rolled leftward.
 - b. Right roll: Symmetric case of left roll, returning *right_roll*, the number of steps rolled rightward.
5. Fully justify the trimmed allele sequences:
 - a. To the *reference allele sequence* and *alternate allele sequence*, prepend the *left_roll* bases prior to the trimmed allele position and append the *right_roll* bases after the trimmed allele position.
 - b. Decrement *start* by *left_roll* and increment *end* by *right_roll*.
6. Construct and return a new Allele with the current *start*, *end*, and *alternate allele sequence*.

¹ Holmes, J. B., Moyer, E., Phan, L., Maglott, D. & Kattman, B. L. *SPDI: Data Model for Variants and Applications at NCBI*. Bioinformatics (2020 March 15). doi:10.1093/bioinformatics/btz856

Table 2: **VRS Justified Normalization** A demonstration of fully justifying an insertion allele.

Steps	<i>start</i> and <i>end</i> (interbase) and allele sequences	Equivalent representations
0. Given allele $S:g.5_6delinsCAGCA$ defined on reference sequence $S=TCAGCAGCT$	(4,6) ("CA", "CAGCA")	$TCAG\left[\frac{CA}{CAGCA}\right]GCT$
1. Trimming a. Remove suffix common to all alleles, if any, and update end position. b. Remove prefix common to all alleles, if any, and update start position. Note: This example shows removing C prefix and A suffix. Equivalently in this case, CA prefix or CA suffix could be removed.	(5,5) ("", "AGC")	$TCAGC\left[\frac{}{AGC}\right]AGCT$
2. & 3. These conditions are False.		
4a. Roll Left Begin with trimmed alleles from (1). While the terminal base of all non-empty alleles equals the base prior to the current position, circularly permute all alleles right one step and move the start left one position. Shown: The 4 incremental steps of rolling left.	(1,1) ("", "CAG")	$TCAGC\left[\frac{}{AGC}\right]AGCT$ $TCAG\left[\frac{}{CAG}\right]CAGCT$ $TCA\left[\frac{}{GCA}\right]GCAGCT$ $TC\left[\frac{}{AGC}\right]AGCAGCT$ $T\left[\frac{}{CAG}\right]CAGCAGCT$ $\Rightarrow left_roll = 4$
4b. Roll Right Symmetric case of step 4a.	(8,8) ("", "AGC")	$TCAGC\left[\frac{}{AGC}\right]AGCT$ $TCAGCA\left[\frac{}{GCA}\right]GCT$ $TCAGCAG\left[\frac{}{CAG}\right]CT$ $TCAGCAGC\left[\frac{}{AGC}\right]T$ $\Rightarrow right_roll = 3$
5. Update position and alleles to fully justify within region of ambiguity. To each trimmed allele from (1), prepend the <i>left_roll</i> preceding reference bases and append the <i>right_roll</i>	(1,8) ("CAGCAGC", "CAGCAGCAGC")	$T\left[\frac{CAGCAGC}{CAGCAGCAGC}\right]T$
4.2. Normalization reference bases (corresponding to the interbase reference spans (1,5) and (5,8) respectively). Decrement the start position by <i>left_roll</i> , and increment the end position by <i>right_roll</i> .

4.3 Computed Identifiers

VRS provides an algorithmic solution to deterministically generate a globally unique identifier from a VRS object itself. All valid implementations of the VRS Computed Identifier will generate the same identifier when the objects are identical, and will generate different identifiers when they are not. The VRS Computed Digest algorithm obviates centralized registration services, allows computational pipelines to generate “private” ids efficiently, and makes it easier for distributed groups to share data.

A VRS Computed Identifier for a VRS concept is computed as follows:

- The object SHOULD be *normalized*. Normalization formally applies to all VRS classes.
- Generate binary data to digest. If the object is a *Sequence* string, encode it using UTF-8. Otherwise, serialize the object using *Digest Serialization*.
- *Generate a truncated digest* from the binary data.
- *Construct an identifier* based on the digest and object type.

Important: Normalizing objects is **STRONGLY RECOMMENDED** for interoperability. While normalization is not strictly required, automated validation mechanisms are anticipated that will likely disqualify Variation that is not normalized. See *Implementations should normalize* for a rationale.

The following diagram depicts the operations necessary to generate a computed identifier. These operations are described in detail in the subsequent sections.

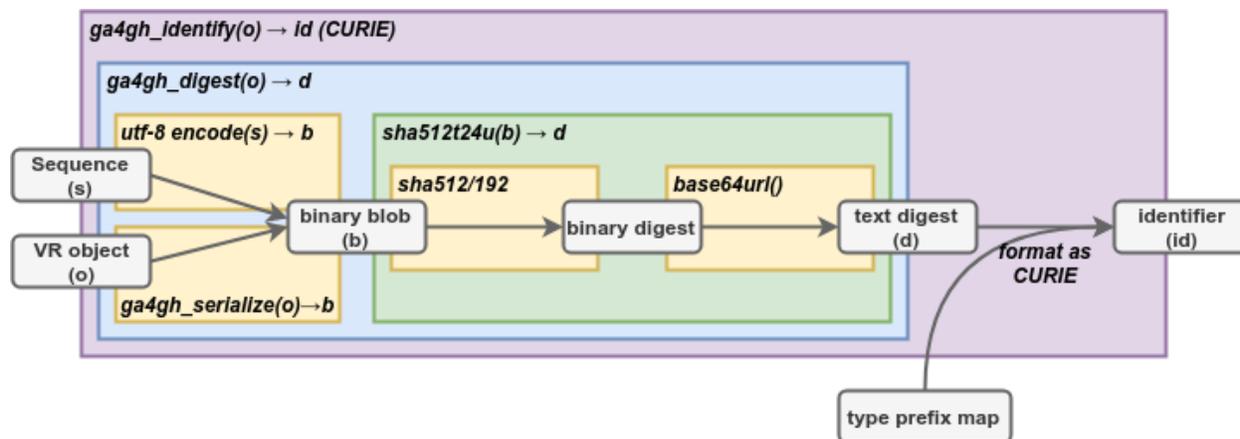

Fig. 1: Serialization, Digest, and Computed Identifier Operations

Entities are shown in gray boxes. Functions are denoted by bold italics. The yellow, green, and blue boxes, corresponding to the `sha512t24u`, `ga4gh_digest`, and `ga4gh_identify` functions respectively, depict the dependencies among functions. `SHA512/192` is `SHA-512` truncated at 192 bits using the systematic name recommended by `SHA-512` (§5.3.6). `base64url` is the official name of the variant of `Base64` encoding that uses a URL-safe character set. [figure source]

Note: Most implementation users will need only the `ga4gh_identify` function. We describe the `ga4gh_serialize`, `ga4gh_digest`, and `sha512t24u` functions here primarily for implementers.

4.3.1 Requirements

Implementations MUST adhere to the following requirements:

- Implementations MUST use the normalization, serialization, and digest mechanisms described in this section when generating GA4GH Computed Identifiers. Implementations MUST NOT use any other normalization, serialization, or digest mechanism to generate a GA4GH Computed Identifier.
- Implementations MUST ensure that all nested objects are identified with GA4GH Computed Identifiers. Implementations MAY NOT reference nested objects using identifiers in any namespace other than `ga4gh`.

Note: The GA4GH schema MAY be used with identifiers from any namespace. For example, a `SequenceLocation` may be defined using a `sequence_id = refseq:NC_000019.10`. However, an implementation of the Computed Identifier algorithm MUST first translate sequence accessions to GA4GH `SQ` accessions to be compliant with this specification.

4.3.2 Digest Serialization

Digest serialization converts a VRS object into a binary representation in preparation for computing a digest of the object. The Digest Serialization specification ensures that all implementations serialize variation objects identically, and therefore that the digests will also be identical. [VRS](#) provides validation tests to ensure compliance.

Important: Do not confuse Digest Serialization with JSON serialization or other serialization forms. Although Digest Serialization and JSON serialization appear similar, they are NOT interchangeable and will generate different GA4GH Digests.

Although several proposals exist for serializing arbitrary data in a consistent manner ([[Gibson](#)], [[OLPC](#)], [[JCS](#)]), none have been ratified. As a result, [VRS](#) defines a custom serialization format that is consistent with these proposals but does not rely on them for definition; it is hoped that a future ratified standard will be forward compatible with the process described here.

The first step in serialization is to generate message content. If the object is a string representing a *Sequence*, the serialization is the UTF-8 encoding of the string. Because this is a common operation, implementations are strongly encouraged to precompute GA4GH sequence identifiers as described in *Required External Data*.

If the object is a composite VRS object, implementations MUST:

- ensure that objects are referenced with identifiers in the `ga4gh` namespace
- replace nested identifiable objects (i.e., objects that have `id` properties) with their corresponding *digests*
- order arrays of digests and ids by Unicode Character Set values
- filter out fields that start with underscore (e.g., `_id`)
- filter out fields with null values

The second step is to JSON serialize the message content with the following REQUIRED constraints:

- encode the serialization in UTF-8
- exclude insignificant whitespace, as defined in [RFC8259§2](#)
- order all keys by Unicode Character Set values
- use two-char escape codes when available, as defined in [RFC8259§7](#)

The criteria for the digest serialization method was that it must be relatively easy and reliable to implement in any common computer language.

Example

```
allele = models.Allele(location=models.SequenceLocation(
    sequence_id="ga4gh:SQ.IIB53T8CNeJJdUqzn9V_JnRtQadwWCb1",
    interval=simple_interval),
    state=models.SequenceState(sequence="T"))
ga4gh_serialize(allele)
```

Gives the following *binary* (UTF-8 encoded) data:

```
{"location": "u5fspwVbQ79QkX6GHLF8tXPCAXFJqRPx", "state": {"sequence": "T", "type":
↪ "SequenceState"}, "type": "Allele"}
```

For comparison, here is one of many possible JSON serializations of the same object:

```
allele.for_json()
```

```
{
  "location": {
    "interval": {
      "end": 44908822,
      "start": 44908821,
      "type": "SimpleInterval"
    },
    "sequence_id": "ga4gh:SQ.IIB53T8CNeJJdUqzn9V_JnRtQadwWCb1",
    "type": "SequenceLocation"
  },
  "state": {
    "sequence": "T",
    "type": "SequenceState"
  },
  "type": "Allele"
}
```

4.3.3 Truncated Digest (sha512t24u)

The sha512t24u truncated digest algorithm computes an ASCII digest from binary data. The method uses two well-established standard algorithms, the [SHA-512](#) hash function, which generates a binary digest from binary data, and [Base64](#) URL encoding, which encodes binary data using printable characters.

Computing the sha512t24u truncated digest for binary data consists of three steps:

1. Compute the [SHA-512](#) digest of a binary data.
2. Truncate the digest to the left-most 24 bytes (192 bits). See *Truncated Digest Timing and Collision Analysis* for the rationale for 24 bytes.
3. Encode the truncated digest as a [base64url](#) ASCII string.

```
>>> import base64, hashlib
>>> def sha512t24u(blob):
    digest = hashlib.sha512(blob).digest()
    tdigest = digest[:24]
    tdigest_b64u = base64.urlsafe_b64encode(tdigest).decode("ASCII")
```

(continues on next page)

(continued from previous page)

```

return tdigest_b64u
>>> sha512t24u(b"ACGT")
'aKF498dAxcJAqme6QYQ7EZ07-fiw8Kw2'

```

4.3.4 Identifier Construction

The final step of generating a computed identifier for a VRS object is to generate a [W3C CURIE](#) formatted identifier, which has the form:

```
prefix ":" reference
```

The GA4GH VRS constructs computed identifiers as follows:

```
"ga4gh" ":" type_prefix "." <digest>
```

Warning: Do not confuse the W3C CURIE prefix (“ga4gh”) with the type prefix.

Type prefixes used by VRS are:

type_prefix	VRS class name
SQ	Sequence
VA	Allele
VH	Haplotype
VS	VariationSet
VSL	SequenceLocation
VCL	ChromosomeLocation
VT	Text

For example, the identifier for the allele example under *Digest Serialization* gives:

```
ga4gh:VA.EgHPXXhULTwoP4-ACfs-YCXaeUQJBjH_
```

4.3.5 References

4.4 Example

This section provides a complete, language-neutral example of essential features of VR. In this example, we will translate an HGVS-formatted variant, `NC_000013.11:g.32936732G>C`, into its VR format and assign a globally unique identifier.

4.4.1 Translate HGVS to VR

Polymorphism in VR

VRS uses polymorphism extensively in order to provide a coherent top-down structure for variation while enabling precise models for variation data.

For example, *Allele* is a kind of *Variation*, *SequenceLocation* is a kind of *Location*, and *SequenceState* is a kind of *State*. See *Future Plans* for the roadmap of VRS data classes and relationships.

All VRS objects contain a `type` attribute, which is used to discriminate polymorphic objects.

The hgvs string `NC_000013.11:g.32936732G>C` represents a single base substitution on the reference sequence `NC_000013.11` (human chromosome 13, assembly GRCh38) at position 32936732 from the reference nucleotide `G` to `C`.

In VRS, a contiguous change is represented using an *Allele* object, which is composed of a *Location* and of the *State* at that location. *Location* and *State* are abstract concepts: VRS is designed to accommodate many kinds of *Locations* based on sequence position, gene names, cytogenetic bands, or other ways of describing locations. Similarly, *State* may refer to a specific sequence change, copy number change, or complex sequence event.

In this example, we will use a *SequenceLocation*, which is composed of a sequence identifier and a *SimpleInterval*.

In VRS, all identifiers are a **Compact URI (CURIE)**. Therefore, `NC_000013.11` MUST be written as the string `refseq:NC_000013.11` to make explicit that this sequence is from `RefSeq`. VRS does not restrict which data sources may be used, but does recommend using prefixes from `identifiers.org`.

VRS uses *Interbase Coordinates*. *Interbase coordinates* always use intervals to refer to sequence spans. For the purposes of this example, *interbase coordinates* look like the more familiar 0-based, right-open numbering system. (Please read about *Interbase Coordinates* if you are interested in the significant advantages of this design choice over other coordinate systems.)

The *SimpleInterval* for the position 32936732 is

```
{
  "end": 32936732,
  "start": 32936731,
  "type": "SimpleInterval"
}
```

The interval is then ‘placed’ on a sequence to create the *SequenceLocation*:

```
{
  "interval": {
    "end": 32936732,
    "start": 32936731,
    "type": "SimpleInterval"
  },
  "sequence_id": "refseq:NC_000013.11",
  "type": "SequenceLocation"
}
```

A *SequenceState* objects consists simply of the replacement sequence, as follows:

```
{
  "sequence": "C",
  "type": "SequenceState"
}
```

We are now in a position to construct an *Allele* object using the objects defined above:

```
{
  "location": {
    "interval": {
      "end": 32936732,
```

(continues on next page)

(continued from previous page)

```

    "start": 32936731,
    "type": "SimpleInterval"
  },
  "sequence_id": "refseq:NC_000013.11",
  "type": "SequenceLocation"
},
"state": {
  "sequence": "C",
  "type": "SequenceState"
},
"type": "Allele"
}

```

This Allele is a fully-compliant VRS object that is parsable using the VRS JSON Schema.

Note: VRS is verbose! The goal of VRS is to provide an extensible framework for representation of sequence variation in computers. VRS objects are readily parsable and have precise meaning, but are often larger than other representations and are typically less readable by humans. This tradeoff is intentional!

4.4.2 Generate a computed identifier

A key feature of VRS is an easily-implemented algorithm to generate computed, digest-based identifiers for variation objects. This algorithm permits organizations to generate the same identifier for the same allele without prior coordination, which in turn facilitates sharing, obviates centralized registration services, and enables identifiers to be used in secure settings (such as diagnostic labs).

Generating a computed identifier requires that all nested objects also use computed identifiers. In this example, the sequence identifier **MUST** be transformed into a digest-based identifier as described in *Computed Identifiers*. In practice, implementations **SHOULD** precompute sequence digests or **SHOULD** use an existing service that does so. (See *Required External Data* for a description of data that are needed to implement VR.) In this case, `refseq:NC_000013.11` maps to `ga4gh:SQ._0wi-qoDrvram155UmcSC-zA5ZK4fpLT`. All VRS computed identifiers begin with the `ga4gh` prefix and use a type prefix (`SQ`, here) to denote the type of object. The VRS sequence identifier is then substituted directly into the Allele's location object:

```

{
  "location": {
    "interval": {
      "end": 32936732,
      "start": 32936731,
      "type": "SimpleInterval"
    },
    "sequence_id": "ga4gh:SQ._0wi-qoDrvram155UmcSC-zA5ZK4fpLT",
    "type": "SequenceLocation"
  },
  "state": {
    "sequence": "C",
    "type": "SequenceState"
  },
  "type": "Allele"
}

```

This, too, is a valid VRS Allele.

Note: Using VRS sequence identifiers collapses differences between alleles due to trivial differences in reference naming. The same variation reported on NC_000013.11, CM000675.2, GRCh38:13, GRCh38.p13:13 would appear to be distinct variation; using a digest identifier will ensure that variation is reported on a single sequence identifier. Furthermore, using digest-based sequence identifiers enables the use of custom reference sequences.

The first step in constructing a computed identifier is to create a binary digest serialization of the Allele. Details are provided in *Computed Identifiers*. For this example the binary object looks like:

```
'{"location":"v9K0mcjQVugxTDIcdi7GBJ_R6fZ1lsYq","state":{"sequence":"C","type":
↪"SequenceState"},"type":"Allele"}'
(UTF-8 encoded)
```

Important: The binary serialization is governed by constraints that guarantee that different implementations will generate the same binary “blob”. Do not confuse binary digest serialization with JSON serialization, which is used elsewhere with VRS schema.

The GA4GH digest for the above blob is computed using the first 192 bits (24 bytes) of the [SHA-512](#) digest, [base64url](#) encoded. Conceptually, the function is:

```
base64url( sha512( blob )[:24] )
```

In this example, the value returned is `n9ax-9x6gOC00Et73VMYqCBfqfxG1XUH`.

A GA4GH Computed Identifier has the form:

```
"ga4gh" ":" <type_prefix> "." <digest>
```

The `type_prefix` for a VRS Allele is `VA`, which results in the following computed identifier for our example:

```
ga4gh:VA.n9ax-9x6gOC00Et73VMYqCBfqfxG1XUH
```

Variation and Location objects contain an OPTIONAL `_id` attribute which implementations may use to store any CURIE-formatted identifier. *If* an implementation returns a computed identifier with objects, the object might look like the following:

```
{
  "_id": "ga4gh:VA.n9ax-9x6gOC00Et73VMYqCBfqfxG1XUH",
  "location": {
    "interval": {
      "end": 32936732,
      "start": 32936731,
      "type": "SimpleInterval"
    },
    "sequence_id": "ga4gh:SQ._0wi-qoDrvram155UmcSC-zA5ZK4fpLT",
    "type": "SequenceLocation"
  },
  "state": {
    "sequence": "C",
    "type": "SequenceState"
  },
  "type": "Allele"
}
```

This example provides a full VR-compliant Allele with a computed identifier.

Note: The `_id` attribute is optional. If it is used, the value **MUST** be a CURIE, but it does **NOT** need to be a GA4GH Computed Identifier. Applications **MAY** choose to implement their own identifier scheme for private or public use. For example, the above `_id` could be a serial number assigned by an application, such as `acmecorp:v0000123`.

4.4.3 What's Next?

This example has shown a full example for a relatively simple case. VRS provides a framework that will enable much more complex variation. Please see *Future Plans* for a discussion of variation classes that are intended in the near future.

The *Implementations* section lists libraries and packages that implement VRS.

VRS objects are *value objects*. An important consequence of this design choice is that data should be associated *with* VRS objects via their identifiers rather than embedded *within* those objects. The appendix contains an example of *associating annotations with variation*.

Note: VRS follows [Semantic Versioning 2.0](#). For a version number MAJOR.MINOR.PATCH:

- MAJOR version is incremented for incompatible API changes.
- MINOR version is incremented for new, backwards-compatible functionality. For VRS, this means changes that add support for new types of variation or extend existing types.
- PATCH version is incremented for bug fixes. For VRS, examples are clarifications of documentation and bug fixes on property constraints. No changes to information models will occur in PATCH releases.

All planned work The [VRS Roadmap](#) for upcoming developments. All currently planned work will be MINOR updates according to the guidelines above.

5.1 1.1

5.1.1 1.1.2

This patch version makes the following corrections and clarifications:

- Adds the intended ChromosomeLocation prefix to the Computed Identifiers table.
- Revises the Cytoband information model to align with ISCN conventions.
- Updates the Cytoband regex to match the specified model.

5.1.2 1.1.1

This patch version makes the following corrections and clarifications:

- Correct styling / indexing of CytobandLocation in restructuredText to match the current Schema and ER Diagram.

- Remove erroneous bracket notation after CURIE from the *locations* attribute in the *Allele* information model.
- Revised Note in interbase design decision to acknowledge community terms.

5.1.3 1.1.0

1.1.0 is the second release of VRS.

New classes

- **ChromosomeLocation**: A region of a chromosomed specified by species and name using cytogenetic naming conventions
- **CytobandInterval**: A contiguous region specified by chromosomal bands features.
- **Haplotype**: A set of zero or more Alleles.
- **VariationSet**: A set of Variation objects.

Other data model changes

- **Interval** was renamed to **SequenceInterval**. **Interval** was an internal class that was never instantiated, so this change should not be visible to users.

Documentation changes

- Added *Relationship of VRS to existing standards* to describe how VRS relates to other standards.
- Updated *Normalization* to clarify handling of reference alleles and generalize terminology to apply to all VRS objects.
- Updated current and future schema diagrams.
- Included a discussion of the *Release Cycle*.

5.2 1.0

5.2.1 1.0.0

VRS 1.0.0 was the first public release of the Variation Representation Specification.

6.1 Relationship of VRS to existing standards

Because a primary objective of the GA4GH Variation Representation Specification (VRS) effort is to unify disparate efforts to represent biological sequence variation, it is important to describe how this document relates to previous work in order to avoid “reinventing the wheel”.

The Variant Call Format (VCF) is the de facto standard for representing alleles, particularly for use during primary analysis in high-throughput sequencing pipelines. VCF permits a wide range of annotations on alleles, such as quality and likelihood scores. VCF is a file-based format and is exclusively for genomic alleles. In contrast, the VRS data model abstractly represents Alleles, Haplotypes, and Genotypes on all sequence types, is independent of medium, and is well-suited to secondary analyses, allele interpretation, aggregation, and system-level interoperability.

The HGVS nomenclature recommendations describe how sequence variation should be presented to human beings. In addition to representing a wide variety of sequence changes from single residue variation through large cytogenetic events, HGVS attempts to also encode in strings notions of biological mechanism (e.g., inversion as a kind of deletion-insertion event), predicted events (e.g., parentheses for computing protein sequence), and complex states (e.g., mosaicism). In practice, HGVS recommendations are difficult to implement fully and consistently, leading to ambiguity in presentation. In contrast, the VRS is a formal specification that improves consistency of representation among computer systems. VRS is currently less expressive than HGVS for rarer cases of variation, such as cytogenetic variation or context-based allele representations (e.g., insT written as dupT when the insertion follows a T). Future versions of the specification will seek to address limitations while preserving principles of conceptual clarity and precision.

The Sequence Ontology (SO) is a set of terms and relationships used to describe the features and attributes of biological sequence. The focus of the SO has been the annotation of, or placement of ‘meaning’, onto genomic sequence regions. The VRS effort seeks to use the same descriptive definitions where possible, and to inform the refinement of SO.

The Genotype Ontology (GENO) builds on the SO to include richer modeling of genetic variation at different levels of granularity that are captured in genotype representations. Unlike the SO which is used primarily for annotation of genomic features, GENO was developed by the Monarch Initiative to support semantic data models for integrated representation of genotypes and genetic variants described in human and model organism databases. The core of the GENO model decomposes a genotype specifying sequence variation across an entire genome into smaller components of variation (e.g. allelic composition at a particular locus, haplotypes, gene alleles, and specific sequence alterations).

GENO also enables description of biological attributes of these genetic entities (e.g. zygosity, phase, copy number, parental origin, genomic position), and their causal relationships with phenotypes and diseases.

ClinVar is an archive of clinically reported relationships between variation and phenotypes along with interpretations and supporting evidence. Data in ClinVar are submitted primarily by diagnostic labs. ClinVar includes expert reviews and data links to other clinically-relevant resources at NCBI. The VRS specification is expected to facilitate data submissions by providing unified guidelines for data structure and allele normalization.

ClinGen provides a centralized database of genomic and phenotypic data provided by clinicians, researchers, and patients. It standardizes clinical annotation and interpretation of genomic variants and provides evidence-based expert consensus for curated genes and variants. ClinGen has informed the VRS effort and is committed to harmonizing and collaborating on the evolution of the VRS specification to achieve improved data sharing.

HL7 FHIR Genomics, Version 2 Clinical Genomics Implementation Guide, CDA Genetic Test Report: There are several standards developed under the HL7 umbrella that include a genomics component. The FHIR Genomics component was released as part of the overall FHIR specification (latest is Release 3) based on standardized use cases. The HL7 Clinical Genomics (CG) Work Group focuses on developing standards for clinical genomic data and related relevant information within EHRs. The specifications developed by the CG work group primarily utilize the HL7 v2 messaging standard and the newer HL7 FHIR (Fast Healthcare Interoperability Resources) framework.

The SPDI format created to represent alleles in NCBI's Variation Services has four components: the sequence identifier, which is specified with a sequence accession and version; the 0-based interbase coordinate where the deletion starts; the deleted sequence (or its length) and the inserted sequence. The Variation Services return the minimum deleted sequence required to avoid over precision. For example, a deletion of one G in a run of 4 is specified with deleted and inserted sequences of GGGG and GGG respectively, avoiding the need to left or right shift the minimal representation. This reduces ambiguity, but can lead to long allele descriptions.

6.2 Associating Annotations with VRS Objects

This example demonstrates how to associate information with VR objects. Although the examples use the [GA4GH VR Python Implementation](#) library, the principles apply regardless of implementation.

Information is never embedded within VRS objects. Instead, it is associated with those objects by means of their ids. This approach to annotations scales better in size and distributes better across multiple data sources.

```
import collections
from ga4gh.vr import ga4gh_identify, models
from ga4gh.vr.dataproxy import SeqRepoRESTDataProxy
from ga4gh.vr.extras.translator import Translator

# Requires seqrepo REST interface is running on this URL (e.g., using docker image)
seqrepo_rest_service_url = "http://localhost:5000/seqrepo"
dp = SeqRepoRESTDataProxy(base_url=seqrepo_rest_service_url)

tlr = Translator(data_proxy=dp)
```

```
# Declare some data as human-readable RS id labels with HGVS expressions
data = (
    ("rs7412C", "NC_000019.10:g.44908822="),
    ("rs7412T", "NC_000019.10:g.44908822C>T"),
    ("rs429358C", "NC_000019.10:g.44908684="),
    ("rs429358T", "NC_000019.10:g.44908684T>C")
)
```

```

# Parse the HGVS expressions and generate three dicts:
# alleles[allele_id]  allele object
# rs_names[allele_id]  rs label
# hgvs_name[allele_id]  original hgvs expression

# For convenience, also build
# rs_to_id[rs_name]  allele_id

alleles = {}
rs_names = {}
hgvs_names = collections.defaultdict(lambda: dict())
for rs, hgvs_expr in data:
    allele = tlr.from_hgvs(hgvs_expr)
    allele_id = ga4gh_identify(allele)
    alleles[allele_id] = allele
    hgvs_names[allele_id] = hgvs_expr
    rs_names[allele_id] = rs

rs_to_id = {r: i for i, r in rs_names.items()}

```

```

# Now, build a new set of annotations: allele frequencies
# This is more complicated because it maps to a map of frequencies
# It should be clear that other frequencies could be easily added here
# or as a separate data source
freqs = {
    "gnomad": {
        "global": {
            rs_to_id["rs7412C"]: 0.9385,

6.3 Design Decisions

VRS contributors confronted numerous trade-offs in developing this specification. As these trade-offs may not be apparent to outside readers, this section highlights the most significant ones and the rationale for our design decisions, including:

6.3.1 Variation Rather than Variant

The abstract *Variation* class is intentionally not labeled “Variant”, despite this being the primary term used in other molecular variation exchange formats (e.g. Variant Call Format, HGVS Sequence Variant Nomenclature). This is because the term “Variant” as used in the Genetics community is intended to describe discrete changes in nucleotide / amino acid sequence. “Variation”, in contrast, captures other classes of molecular variation, including epigenetic alteration and transcript abundance. Capturing these other classes of variation is a *future goal* of VRS, as there are many annotations that will require these variation classes as the subject.

6.3.2 Allele Rather than Variant

The most primitive sequence assertion in VRS is the *Allele* entity. Colloquially, the words “allele” and “variant” have similar meanings and they are often used interchangeably. However, the VR contributors believe that it is essential to distinguish the state of the sequence from the change between states of a sequence. It is imperative that precise terms

are used when modelling data. Therefore, within VRS, Allele refers to a state and “variant” refers to the change from one Allele to another.

The word “variant”, which implies change, makes it awkward to refer to the (unchanged) reference allele. Some systems will use an HGVS-like syntax (e.g., NC_000019.10:g.44906586G>G or NC_000019.10:g.44906586=) when referring to an unchanged residue. In some cases, such “variants” are even associated with allele frequencies. Similarly, a predicted consequence is better associated with an allele than with a variant.

6.3.3 Implementations should normalize

VRS STRONGLY RECOMMENDS that Alleles be *normalized* when generating *computed identifiers*. The rationale for recommending, rather than requiring, normalization is grounded in dual views of Allele objects with distinct interpretations:

- Allele as minimal representation of a change in sequence. In this view, normalization is a process that makes the representation minimal and unambiguous.
- Allele as an assertion of state. In this view, it is reasonable to want to assert state that may include (or be composed entirely of) reference bases, for which the normalization process would alter the intent.

Although this rationale applies only to Alleles, it may have parallels with other VRS types. In addition, it is desirable for all VRS types to be treated similarly.

Furthermore, if normalization were required in order to generate *Computed Identifiers*, but did not apply to certain instances of VRS Variation, implementations would likely require secondary identifier mechanisms, which would undermine the intent of a global computed identifier.

The primary downside of not requiring normalization is that Variation objects might be written in non-canonical forms, thereby creating unintended degeneracy.

Therefore, normalization of all VRS Variation classes is optional in order to support the view of Allele as an assertion of state on a sequence.

6.3.4 Alleles are Fully Justified

In order to standardize the representation of sequence variation, Alleles SHOULD be fully justified from the description of the NCBI [Variant Overprecision Correction Algorithm \(VOCA\)](#). Furthermore, normalization rules are identical for all sequence types (DNA, RNA, and protein).

The choice of algorithm was relatively straightforward: VOCA is published, easily understood, easily implemented, and covers a wide range of cases.

The choice to fully justify is a departure from other common variation formats. The HGVS nomenclature recommendations, originally published in 1998, require that alleles be right normalized (*3' rule*) on all sequence types. The Variant Call Format (VCF), released as a PDF specification in 2009, made the conflicting choice to write variants *left (5')* normalized and anchored to the previous nucleotide.

Fully-justified alleles represent an alternate approach. A fully-justified representation does not make an arbitrary choice of where a variant truly occurs in a low-complexity region, but rather describes the final and unambiguous state of the resultant sequence.

6.3.5 Interbase Coordinates

Sequence ranges use an interbase coordinate system. Interbase coordinate conventions are used in this terminology because they provide conceptual consistency that is not possible with residue-based systems.

Important: The choice of what to count—base or interbase positions—has significant semantic implications for coordinates. In some circumstances, interbase coordinates and the corresponding base coordinates are numerically identical. We intentionally avoid describing the interbase coordinate system as “0-based” (a popular community term, as is “space-based”) to help reduce confusion on the meaning of the coordinates used in VRS.

When humans refer to a range of residues within a sequence, the most common convention is to use an interval of ordinal residue positions in the sequence. While natural for humans, this convention has several shortcomings when dealing with sequence variation.

For example, interval coordinates are interpreted as exclusive coordinates for insertions, but as inclusive coordinates for substitutions and deletions; in effect, the interpretation of coordinates depends on the variant type, which is an unfortunate coupling of distinct concepts.

6.3.6 Modelling Language

The VRS collaborators investigated numerous options for modelling data, generating code, and writing the wire protocol. Required and desired selection criteria included:

- language-neutral – or at least C/C++, java, python
- high-quality tooling/libraries
- high-quality code generation
- documentation generation
- **supported constructs and data types**
 - typedefs/aliases
 - enums
 - lists, maps, and maps of lists/maps
 - nested objects
- protocol versioning (but not necessarily automatic adaptation)

Initial versions of the VRS logical model were implemented in UML, protobuf, and swagger/OpenAPI, and JSON Schema. We have implemented our schema in JSON Schema. Nonetheless, it is anticipated that some adopters of the VRS logical model may implement the specification in other protocols.

6.3.7 Serialization Strategy

There are many packages and proposals that aspire to a canonical form for json in many languages. Despite this, there are no ratified or *de facto* winners. Many packages have similar names, which makes it difficult to discern whether they are related or not (often not). Although some packages look like good single-language candidates, none are ready for multi-language use. Many seem abandoned. The need for a canonical json form is evident, and there was at least one proposal for an ECMA standard.

Therefore, we implemented our own *serialization format*, which is very similar to [Gibson Canonical JSON](#) (not to be confused with [OLPC Canonical JSON](#)).

6.3.8 Not using External Chromosome Declarations

In *ChromosomeLocation*, the tuple <species,chromosome name> refers an archetypal chromosome for the species. [WikiData](#) and [MeSH](#) provide such definitions (e.g., Human Chr 1 at [WikiData](#) and [MeSH](#)) and were considered, and rejected, for use in VRS. Both ontologies were anticipated to increase complexity that was not justified by the benefit to VRS. In addition, data in WikiData are crowd-sourced and therefore potentially unstable, and the species coverage in MeSH was insufficient for anticipated VRS uses.

6.4 Development Process

6.4.1 Release Cycle

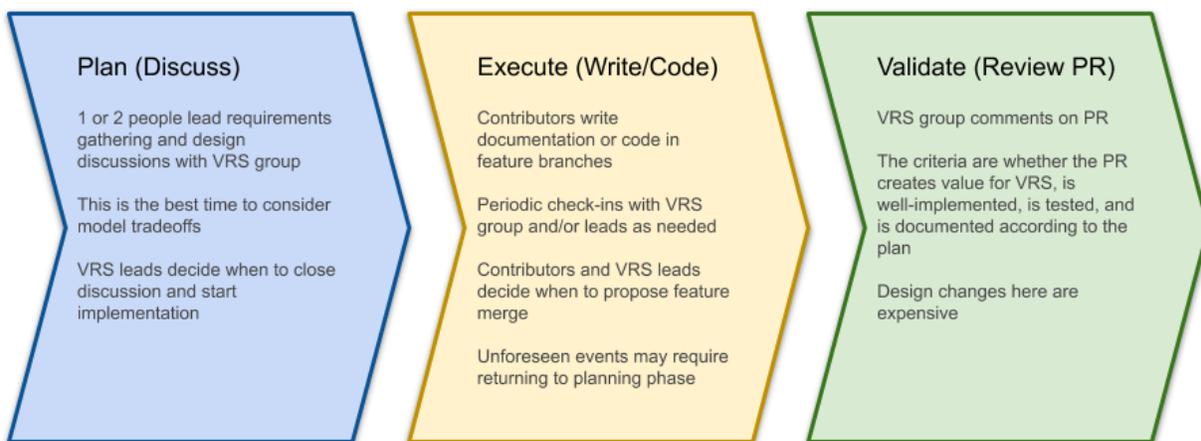

Fig. 1: The VRS development process.

The release cycle is implemented in the [VR project board](#), which is the authoritative source of information about development status.

Planned Features

Feature requests from the community are made through the generation of [GitHub issues on the VRS repository](#), which are open for public review and discussion.

Project Leadership Review

Open issues are reviewed and triaged by the *Project Leadership*. Feature requests identified to support an unmet need are added to the [Backburner](#) project column and scheduled for discussion in our weekly VR calls. These discussions are used to inform whether or not a feature will be planned for development. The *Project Maintainers* are responsible for making the final determination on whether or not a feature should be added to VRS.

Requirements Gathering

Once a planned feature is introduced in call, the issue moves to the [Planning](#) project column. During this phase, community feedback on use cases and technical requirements will be collected (see [example requirement issues](#)). Deadlines for submitting cases will be set by the Project Maintainers.

Requirements Discussion

Once the requirements gathering phase has been completed, the issue moves to the [Backlog/Ready for Dev](#) project column. In this phase, the requirements undergo review and discussion by the community on VR calls.

Feature Development

After community review of requirements, the issue moves on to the [In Progress](#) project column. In this stage, the draft features will be developed as a draft [Pull Request](#) (PR). The draft author will indicate that a feature is ready for community review by marking the PR as “Ready for review” (at which point the PR loses “draft” status).

Feature Review

Once a PR is ready for review, the Project Maintainers will move the corresponding issue to the [QA/Feedback](#) project column. Pull requests ready for public review **MAY** be merged into the master branch by through review and approval by at least one (non-authoring) Project Maintainer. Merged commits **MAY** be tagged as alpha releases when needed. After merging, corresponding issues are moved to the [Done](#) project column and are closed.

Version Review and Release

After completion of all planned features for a new minor or major version, a request for community review will be indicated by a beta release of the new version. Community stakeholders involved in the feature requests and requirements gathering for the included features are notified by Project Maintainers for review and approval of the release. After a community review period of at least two weeks, the Project Leadership will review and address any raised concerns for the reviewed version.

After passing review, new minor versions are released to production. If any features in the reviewed version are deemed to be significant additions to the specification by the Project Leadership, or if it is a major version change, instead a release candidate version will be released and submitted for GA4GH product approval. After approval, the new version is released to production.

VRS follows [GA4GH project versioning recommendations](#), based on [Semantic Versioning 2.0](#). The VRS GitHub repository master branch contains the latest development code for community review (see [Release Cycle](#)).

6.4.2 Leadership

Project Leadership

As a product of the Genomic Knowledge Standards (GKS) Work Stream, project leadership is comprised of the [Work Stream leadership](#):

- Alex Wagner (@ahwagner)
- Andy Yates (@andrewyatz)
- Bob Freimuth (@rrfreimuth)
- Javier Lopez (@javild)
- Larry Babb (@larrybabb)
- Matt Brush (@mbrush)
- Melissa Konopko (@MKonopko)
- Reece Hart (@reece)

Project Maintainers

Project maintainers are the leads of the GKS Variation Representation working group:

- Alex Wagner (@ahwagner)
- Larry Babb (@larrybabb)
- Reece Hart (@reece)

6.5 Future Plans

6.5.1 Overview

VRS covers a fundamental subset of data types to represent variation, thus far predominantly related to the replacement of a subsequence in a reference sequence. Increasing its applicability will require supporting more complex types of variation, including:

- alternative coordinate types such as nested ranges
- feature-based coordinates such as genes, cytogenetic bands, and exons
- copy number variation
- structural variation
- mosaicism and chimerism
- rule-based variation

The following sections provide a preview of planned concepts under way to address a broader representation of variation.

6.5.2 Intervals and Locations

VRS uses *Location (Abstract Class)* subclasses to define where variation occurs. The schema is designed to be extensible to new kinds of Intervals and Locations in order to support, for example, fuzzy coordinates or feature-based locations.

NestedInterval

Biological definition

None

Computational definition

An *SequenceInterval (Abstract Class)* comprised of an *inner* and *outer SimpleInterval*. The *NestedInterval* allows for the definition of “fuzzy” range endpoints by designating a potentially included region (the *outer SimpleInterval*) and required included region (the *inner SimpleInterval*).

Information model

Field	Type	Limits	Description
type	string	1..1	Interval type; MUST be set to ‘ NestedInterval ’
inner	<i>SimpleInterval</i>	1..1	known interval
outer	<i>SimpleInterval</i>	1..1	potential interval

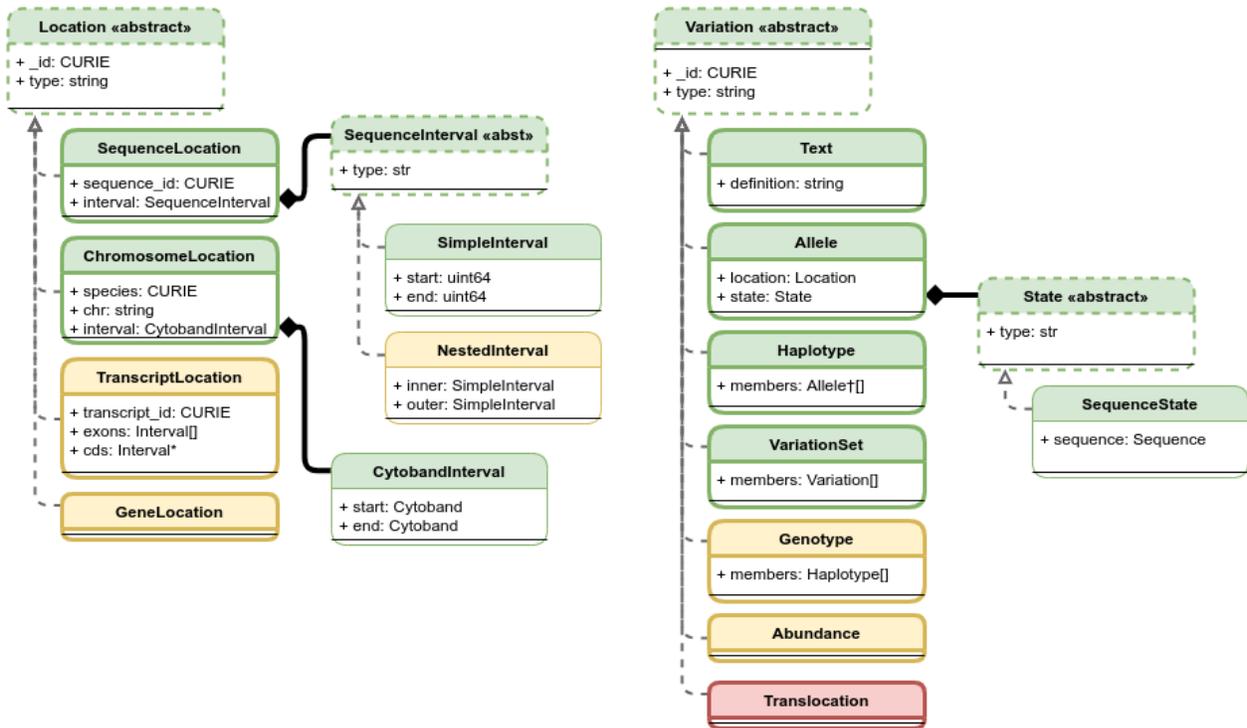

Fig. 2: Planned Variation Representation Specification Schema

See *Current schema diagram* for legend.

Existing classes are colored green. Components that are undergoing testing and evaluation and are candidates for the next release cycle are yellow. Components that are planned but still undergoing requirement gathering and initial development are colored red.

[source]

Implementation guidance

- Implementations **MUST** enforce values 0 *outer.start* *inner.start* *inner.end* *outer.end*. In the case of double-stranded DNA, this constraint holds even when a feature is on the complementary strand.

ComplexInterval**Biological definition**

Representation of complex coordinates based on relative locations or offsets from a known location. Examples include “left of” a given position and intronic positions measured from intron-exon junctions.

Computational definition

Under development.

Information model

Under development.

GeneLocation**Biological definition**

The symbolic location of a gene.

Computational definition

A gene location is made by reference to a gene identifier from NCBI, Ensembl, HGNC, or other public trusted authority.

Information model

Field	Type	Limits	Description
_id	<i>CURIE</i>	0..1	Location Id; MUST be unique within document
type	string	1..1	Location type; MUST be set to ‘ GeneLocation ’
gene_id	<i>CURIE</i>	1..1	CURIE-formatted gene identifier using NCBI numeric gene id.

Notes

- *gene_id* **MUST** be specified as a CURIE, using a CURIE prefix of “*NCBI*” and CURIE reference with the numeric gene id. Other trusted authorities **MAY** be permitted in future releases.

Implementation guidance

- GeneLocations **MAY** be converted to *SequenceLocation* using external data. The source of such data and mechanism for implementation is not defined by this specification.

6.5.3 State Classes

Additional *State (Abstract Class)* concepts that are being planned for future consideration in the specification.

CNVState

Note: This concept is being refined. Please comment at <https://github.com/ga4gh/vr-spec/issues/46>.

Biological definition

Variations in the number of copies of a segment of DNA. Copy number variations cover copy losses or gains and at known or unknown locations (including tandem repeats). Variations MAY occur at precise SequenceLocations, within nested intervals, or at GeneLocations. There is no lower or upper bound on CNV sizes.

Computational definition

Under development.

Information model

Field	Type	Limits	Description
type	string	1..1	State type; MUST be set to 'CNVState'
location	<i>Location (Abstract Class)</i>	1..1	the Location of the copy ('null' if unknown)
min_copies	int	1..1	The minimum number of copies
max_copies	int	1..1	The maximum number of copies

6.5.4 Variation Classes

Additional *Variation* concepts that are being planned for future consideration in the specification. See *Variation* for more information.

Translocations

Note: This concept is being refined. Please comment at <https://github.com/ga4gh/vr-spec/issues/103>

Biological definition

The aberrant joining of two segments of DNA that are not typically contiguous. In the context of joining two distinct coding sequences, translocations result in a gene fusion, which is also covered by this VRS definition.

Computational definition

A joining of two sequences is defined by two *Location (Abstract Class)* objects and an indication of the join “pattern” (advice needed on conventional terminology, if any).

Information model

Under consideration. See <https://github.com/ga4gh/vr-spec/issues/28>.

Examples

t(9;22)(q34;q11) in BCR-ABL

Genotype

Biological definition

The genetic state of an organism, whether complete (defined over the whole genome) or incomplete (defined over a subset of the genome).

Computational definition

A list of Haplotypes.

Information model

Field	Type	Limits	Description
_id	<i>CURIE</i>	0..1	Variation Id; MUST be unique within document
type	string	1..1	Variation type; MUST be set to ' Genotype '
completeness	enum	1..1	Declaration of completeness of the Haplotype definition. Values are: <ul style="list-style-type: none"> • UNKNOWN: Other Haplotypes may exist. • PARTIAL: Other Haplotypes exist but are unspecified. • COMPLETE: The Genotype declares a complete set of Haplotypes.
members	<i>Haplotype</i> [] or <i>CURIE</i> []	0..*	List of Haplotypes or Haplotype identifiers; length MUST agree with ploidy of genomic region

Implementation guidance

- Haplotypes in a Genotype MAY occur at different locations or on different reference sequences. For example, an individual may have haplotypes on two population-specific references.
- Haplotypes in a Genotype MAY contain differing numbers of Alleles or Alleles at different Locations.

Notes

- The term “genotype” has two, related definitions in common use. The narrower definition is a set of alleles observed at a single location and with a ploidy of two, such as a pair of single residue variants on an autosome. The broader, generalized definition is a set of alleles at multiple locations and/or with ploidy other than two. The VRS Genotype entity is based on this broader definition.
- The term “diplotype” is often used to refer to two haplotypes. The VRS Genotype entity subsumes the conventional definition of diplotype. Therefore, the VRS model does not include an explicit entity for diplotypes. See [this note](#) for a discussion.
- The VRS model makes no assumptions about ploidy of an organism or individual. The number of Haplotypes in a Genotype is the observed ploidy of the individual.
- In diploid organisms, there are typically two instances of each autosomal chromosome, and therefore two instances of sequence at a particular location. Thus, Genotypes will often list two Haplotypes. In the case of haploid chromosomes or haploinsufficiency, the Genotype consists of a single Haplotype.

- A consequence of the computational definition is that Haplotypes at overlapping or adjacent intervals MUST NOT be included in the same Genotype. However, two or more Alleles MAY always be rewritten as an equivalent Allele with a common sequence and interval context.
- The rationale for permitting Genotypes with Haplotypes defined on different reference sequences is to enable the accurate representation of segments of DNA with the most appropriate population-specific reference sequence.

Sources

SO: [Genotype \(SO:0001027\)](#) — A genotype is a variant genome, complete or incomplete.

Note: Genotypes represent Haplotypes with arbitrary ploidy The VRS defines Haplotypes as a list of Alleles, and Genotypes as a list of Haplotypes. In essence, Haplotypes and Genotypes represent two distinct dimensions of containment: Haplotypes represent the “in phase” relationship of Alleles while Genotypes represents sets of Haplotypes of arbitrary ploidy.

There are two important consequences of these definitions: There is no single-location Genotype. Users of SNP data will be familiar with representations like rs7412 C/C, which indicates the diploid state at a position. In the VRS, this is merely a special case of a Genotype with two Haplotypes, each of which is defined with only one Allele (the same Allele in this case). The VRS does not define a diplotype type. A diplotype is a special case of a VRS Genotype with exactly two Haplotypes. In practice, software data types that assume a ploidy of 2 make it very difficult to represent haploid states, copy number loss, and copy number gain, all of which occur when representing human data. In addition, assuming ploidy=2 makes software incompatible with organisms with other ploidy. The VRS makes no assumptions about “normal” ploidy.

In other words, the VRS does not represent single-position Genotypes or diplotypes because both concepts are subsumed by the Allele, Haplotype, and Genotypes entities.

6.5.5 Rule-based Variation

Some variations are defined by categorical concepts, rather than specific locations and states. These variations go by many terms, including *categorical variants*, *bucket variants*, *container variants*, or *variant classes*. These forms of variation are not described by any broadly-recognized variation format, but modeling them is a key requirement for the representation of aggregate variation descriptions as commonly found in biomedical literature. Our future work will focus on the formal specification for representing these variations with sets of rules, which we currently call *Rule-based Variation*.

RuleLocation

RuleLocation is a subclass of *Location (Abstract Class)* intended to capture locations defined by rules instead of specific contiguous sequences. This includes locations defined by sequence characteristics, e.g. *microsatellite regions*.

RuleState

RuleState is a subclass of *State (Abstract Class)* intended to capture states defined by categorical rules instead of sequence states. This includes *gain- / loss-of-function*, *oncogenic*, and *truncating* variation.

6.6 Proposal for GA4GH-wide Computed Identifier Standard

This appendix describes a proposal for creating a GA4GH-wide standard for serializing data, computing digests on serialized data, and constructing CURIE identifiers from the digests. Essentially, it is a generalization of the *Computed*

Identifiers section.

This standard is proposed now because VRS needs a well-defined mechanism for generating identifiers. Changing the identifier mechanism later will create significant issues for VR adopters.

6.6.1 Background

The GA4GH mission entails structuring, connecting, and sharing data reliably. A key component of this effort is to be able to *identify* entities, that is, to associate identifiers with entities. Ideally, there will be exactly one identifier for each entity, and one entity for each identifier. Traditionally, identifiers are assigned to entities, which means that disconnected groups must coordinate on identifier assignment.

The computed identifier scheme proposed in VRS computes identifiers from the data itself. Because identifiers depend on the data, groups that independently generate the same variation will generate the same computed identifier for that entity, thereby obviating centralized identifier systems and enabling identifiers to be used in isolated settings such as clinical labs.

The computed identifier mechanism is broadly applicable and useful to the entire GA4GH ecosystem. Adopting a common identifier scheme will make interoperability of GA4GH entities more obvious to consumers, will enable the entire organization to share common entity definitions (such as sequence identifiers), and will enable all GA4GH products to share tooling that manipulate identified data. In short, it provides an important consistency within the GA4GH ecosystem.

As a result, we are proposing that the computed identifier scheme described in VRS be considered for adoption as a GA4GH-wide standard. If the proposal is accepted by the GA4GH executive committee, the current VRS proposal will stand as-is; if the proposal is rejected, the VRS proposal will be modified to rescope the computed identifier mechanism to VR and under administration of the VR team.

6.6.2 Proposal

The following algorithmic processes, described in depth in the VR *Computed Identifiers* proposal, are included in this proposal by reference:

- **GA4GH Digest Serialization** is the process of converting an object to a canonical binary form based on JSON and inspired by similar (but unratified) JSON standards. This serialization for is used only for the purposes of computing a digest.
- **GA4GH Truncated Digest** is a convention for using [SHA-512](#), truncated to 24 bytes, and encoding using `base64url`.
- **GA4GH Identification** is the CURIE-based syntax for constructing a namespaced and typed identifier for an object.

6.6.3 Type Prefixes

A GA4GH identifier is proposed to be constructed according to this syntax:

```
"ga4gh" ":" type_prefix "." digest
```

The *digest* is computed as described above. The `type_prefix` is a short alphanumeric code that corresponds to the type of object being represented. If this proposal is accepted, this “type prefix map” would be administered by GA4GH. (Currently, this map is maintained in a YAML file within the VRS repository, but it would be relocated on approval of this proposal.)

We propose the following guidelines for type prefixes:

- Prefixes SHOULD be short, approximately 2-4 characters.
- Prefixes SHOULD be for concrete types, not polymorphic parent classes.
- A prefix MUST map 1:1 with a schema type.
- Variation Representation types SHOULD start with V.
- Variation Annotation types SHOULD start with A.

6.6.4 Administration

If accepted, administration of these guidelines should be transferred to a technical steering committee. If not accepted, the VR team will assume administration of the existing prefixes.

6.7 Implementations

The libraries and applications listed below have implemented the GA4GH Variation Representation Specification to store and exchange variation data. They are listed here to demonstrate utility and as a resource for those considering implementing VRS. These packages are not supported by GA4GH.

6.7.1 Libraries

Libraries facilitate the use of the VRS, but do not implement a particular use or application. Although there is only one library currently, it is expected that others will eventually appear as VRS is adopted.

vr-python: GA4GH VRS Python Implementation

The [GA4GH VR Python Implementation](#) is an implementation for the GA4GH VRS. It supports all types covered by the VRS, implements Allele normalization and computed identifier generation, and provides “extra” features such as translation from HGVS, SPDI, and VCF formats. See [vr-python notebooks](#) for usage examples.

VRS MAY be used without using the Python implementation.

6.7.2 Applications and Web Services

Applications implement VRS to support specific use cases. Projects known to implement VRS are listed below. Descriptions are provided by the application authors.

ClinGen Allele Registry

ClinGen Allele Registry¹ provides identifiers for more than 900 million variants. Each identifier (canonical allele identifiers: CAIDs) is an abstract concept which represents a group of identical variants based on alignment. Identifiers are retrievable irrespective of the reference sequence and normalization status.

As a Driver Project for GA4GH, [ClinGen Allele Registry](#) implements two standards: RefGet and VRS in the first implementation.

The API endpoints that support data retrieval in this two key standards are summarized in the following table.

HOST: <https://reg.clinicalgenome.org/>

¹ Pawliczek P, Patel RY, et al. *ClinGen Allele Registry links information about genetic variants*. Hum Mutat 11 (2018). doi:10.1002/humu.23637

API Path	Parameters	Response Format	Example
RefGet			
[GET] /sequence/service-info	-	Refget v1.0.0	/sequence/service-info
[GET] /sequence/{id}	id => TRUNC512 digest for reference sequence	Refget v1.0.0	/sequence/vYfm5TA_F-_BtIGjfzjGOj8b6IK5hCTx
[GET] /sequence/{id}/metadata	id => TRUNC512 digest for reference sequence	Refget v1.0.0	/sequence/vYfm5TA_F-_BtIGjfzjGOj8b6IK5hCTx/metadata
VR			
[GET] /vrAllele?hgvs={hgvs}	hgvs => HGVS expression	VRS v1.0	/vrAllele?hgvs=NC_000007.14:g.55181320A>T /vrAllele?hgvs=NC_000007.14:g.55181220del

Support for GA4GH refget and VRS specs provided in ClinGen Allele Registry is independent from VR-Python. Support for this community standards is implemented in ClinGen Allele Registry through extension of code written in C++.

BRCA Exchange

The goal of BRCA Exchange (<https://brcaexchange.org/>) is to expand approaches to integrate and disseminate information on BRCA variants in Hereditary Breast and Ovarian Cancer (HBOC), as an exemplar for additional genes and additional heritable disorders². The BRCA Exchange web portal provides information on the annotation and clinical interpretation of 40,000 variants to date. As a GA4GH Driver Project, BRCA Exchange is contributing to and adopting the Variant Annotation (VA), Pedigree (Ped) and Variant Representation (VRS) standards. BRCA Exchange displays the VRS identifiers of all variants, and provides an API endpoint for querying variants by VRS identifier. With this endpoint, if BRCA Exchange contains a variant that matches the VRS identifier, it returns data on that variant. Otherwise, it returns a Server 500 error.

Example query:

- https://brcaexchange.org/backend/data/vrid?vr_id=ga4gh:VA.jgT2IU4y55WshIgcW__MVzHBnnga_iZL

VICC Meta-knowledgebase

The Variant Interpretation for Cancer Consortium (VICC; <https://cancervariants.org>) has a collection of ~20K clinical interpretations associated with ~3,500 somatic variations and variation classes in a harmonized meta-knowledgebase³ (see documentation at <http://docs.cancervariants.org>). Each interpretation is be linked to one or more variations or a variation class.

As a Driver Project for GA4GH, VICC is contributing to and/or adopting several GA4GH standards, including VRS, Variant Annotation (VA), and service_info. VICC supports queries on all VRS computed identifiers at the searchAssociations endpoint ([vicc-docs](http://docs.cancervariants.org)). Features associated with each interpretation are represented as VRS objects.

Example queries:

- **Allele:** <https://search.cancervariants.org/api/v1/associations?size=10&from=1&q=ga4gh:VA.mJbJssW541oOsOtBoX36Mppr6hMjbjFr>

6.8 Truncated Digest Timing and Collision Analysis

The GA4GH Digest uses a truncated SHA-512 digest in order to generate a unique identifier based on data that defines the object. This notebook discusses the choice of SHA-512 over other digest methods and the choice of truncation length.

Note: Please see this Jupyter notebook in Python SeqRepo library for code and updates.

6.8.1 Conclusions

- The computational time for SHA-512 is similar to that of other digest methods. Given that it is believed to distribute input bits more uniformly with no increased computational cost, it should be preferred for our use (and likely most uses).
- 24 bytes (192 bits) of digest is *ample* for VRS uses. Arguably, we could choose much smaller without significant risk of collision.

```
import hashlib
import math
import timeit

from IPython.display import display, Markdown

from ga4gh.vr.extras.utils import _format_time

algorithms = {'sha512', 'sha1', 'sha256', 'md5', 'sha224', 'sha384'}
```

6.8.2 Digest Timing

This section provides a rationale for the selection of SHA-512 as the basis for the Truncated Digest.

```
def blob(l):
    """return binary blob of length l (POSIX only)"""
    return open("/dev/urandom", "rb").read(l)

def digest(alg, blob):
    md = hashlib.new(alg)
    md.update(blob)
    return md.digest()

def magic_run1(alg, blob):
    t = %timeit -o digest(alg, blob)
    return t
```

(continues on next page)

(continued from previous page)

```
def magic_tfmt(t):
    """format TimeitResult for table"""
    return "{a} ± {s} ({b}, {w})".format(
        a = _format_time(t.average),
        s = _format_time(t.stdev),
        b = _format_time(t.best),
        w = _format_time(t.worst),
    )
```

```
blob_lengths = [100, 1000, 10000, 100000, 1000000]
blobs = [blob(l) for l in blob_lengths]
```

```
table_rows = []
table_rows += [{"algorithm"} + list(map(str, blob_lengths))]
table_rows += [{"-"} * len(table_rows[0])]
for alg in sorted(algorithms):
    r = [alg]
    for i in range(len(blobs)):
        blob = blobs[i]
        t = timeit.timeit(stmt='digest(alg, blob)', setup='from __main__ import alg, _
↳ blob, digest', number=1000)
        r += [_format_time(t)]
    table_rows += [r]
table = "\n".join(["|".join(map(str, row)) for row in table_rows])
display(Markdown(table))
```

algorithm	100	1000	10000	100000	1000000
md5	1.02 ms	2.51 ms	23.4 ms	145 ms	1.44 s
sha1	1.02 ms	1.91 ms	11.3 ms	101 ms	1 s
sha224	1.21 ms	3.16 ms	23.1 ms	224 ms	2.2 s
sha256	1.18 ms	3.29 ms	23.3 ms	223 ms	2.2 s
sha384	1.17 ms	2.54 ms	16 ms	150 ms	1.47 s
sha512	1.2 ms	2.55 ms	16.1 ms	148 ms	1.47 s

Conclusion: SHA-512 computational time is comparable to that of other digest methods.

This result was not expected initially. On further research, there is a clear explanation: The SHA-2 series of digests (which includes SHA-224, SHA-256, SHA-384, and SHA-512) is defined using 64-bit operations. When an implementation is optimized for 64-bit systems (as used for these timings), the number of cycles is essentially halved when compared to 32-bit systems and digests that use 32-bit operations. SHA-2 digests are indeed much slower than SHA-1 and MD5 on 32-bit systems, but such legacy platforms are not relevant to the Truncated Digest.

6.8.3 Collision Analysis

Our question: **For a hash function that generates digests of length b (bits) and a corpus of m messages, what is the probability p that there exists at least one collision?** This is the so-called Birthday Problem [6].

Because analyzing digest collision probabilities typically involve choices of mathematical approximations, multiple “answers” appear online. This section provides a quick review of prior work and extends these discussions by focusing the choice of digest length for a desired collision probability and corpus size.

Throughout the following, we’ll use these variables:

- P = Probability of collision
- P' = Probability of no collision
- b = digest size, in bits
- s = digest space size, $s = 2^b$
- m = number of messages in corpus

The length of individual messages is irrelevant.

- [7] https://en.wikipedia.org/wiki/Birthday_attack

Background: The Birthday Problem

Directly computing the probability of one or more collisions, P , in a corpus is difficult. Instead, we first seek to solve for P' , the probability that a collision does not exist (i.e., that the digests are unique). Because there are only two outcomes, $P + P' = 1$ or, equivalently, $P = 1 - P'$.

For a corpus of size $m = 1$, the probability that the digests of all $m = 1$ messages are unique is (trivially) 1:

$$P' = s/s = 1$$

because there are s ways to choose the first digest from among s possible values without a collision.

For a corpus of size $m = 2$, the probability that the digests of all $m = 2$ messages are unique is:

$$P' = 1 \times \left(\frac{s-1}{s}\right)$$

because there are $s - 1$ ways to choose the second digest from among s possible values without a collision.

Continuing this logic, we have:

$$P' = \prod_{i=0}^{m-1} \frac{(s-i)}{s}$$

or, equivalently,

$$P' = \frac{s!}{s^m \cdot (s-m)!}$$

When the size of the corpus becomes greater than the size of the digest space, the probability of uniques is zero by the pigeonhole principle. Formally, the above equation becomes:

$$P' = \begin{cases} 1 & \text{if } m = 0 \\ \prod_{i=0}^{m-1} \frac{(s-i)}{s} & \text{if } 1 \leq m \leq s \\ 0 & \text{if } m > s \end{cases}$$

For the remainder of this section, we'll focus on the case where $1 \leq m \ll s$. In addition, notice that the brute force computation is not feasible in practice because m and s will be very large (both $\gg 2^9$).

Approximation #1: Taylor approximation of terms of P'

The Taylor series expansion of the exponential function is

$$e^x = 1 + x + \frac{x^2}{2!} + \frac{x^3}{3!} + \dots$$

For $|x| \ll 1$, the expansion is dominated by the first terms and therefore $e^x \approx 1 + x$.

In the above expression for P' , note that the product term $(s - i)/s$ is equivalent to $1 - i/s$. Combining this with the Taylor expansion, where $x = -i/s$ ($m \ll s$):

$$P' \approx \prod_{i=0}^{m-1} e^{-i/s} = e^{-m(m-1)/2s}$$

(The latter equivalence comes from converting the product of exponents to a single exponent of a summation of $-i/s$ terms, factoring out $1/s$, and using the series sum equivalence $\sum_{j=0}^n j = n(n + 1)/2$ for $n \geq 0$.)

Approximation #2: Taylor approximation of P'

The above result for P' is also amenable to Taylor approximation. Setting $x = -m(m - 1)/2s$, we continue from the previous derivation:

$$P' \approx e^{-(m(m-1)/2s)} \approx 1 + \frac{-m(m-1)}{2s}$$

Approximation #3: Square approximation

For large m , we can approximate $m(m - 1)$ as m^2 to yield

$$P' \approx 1 - m^2/2s$$

Summary of equations

We may now summarize equations to approximate the probability of digest collisions.

Table 1: Summary of Equations

Method	Probability of uniqueness(P')	Probability of collision($P = 1 - P'$)	Assumptions	Source/Comparison
exact	$\prod_{i=0}^{m-1} \frac{(s-i)}{s}$	$1 - P'$	$1 \leq m \leq s$	[1]
Taylor approximation #1	$e^{-m(m-1)/2s}$	$1 - P'$	$m \ll s$	[1]
Taylor approximation #2	$1 - \frac{m(m-1)}{2s}$	$\frac{m(m-1)}{2s}$	(same)	[1]
Large square approximation	$1 - \frac{m^2}{2s}$	$\frac{m^2}{2s}$	(same)	[2] (where $s = 2^n$)

- [2] <http://preshing.com/20110504/hash-collision-probabilities/>

6.8.4 Choosing a digest size

Now, we turn the problem around:

What digest length b is required to achieve a collision probability less than P for m messages?

From the above summary, we have $P = m^2/2s$ for $m \ll s$. Rewriting with $s = 2^b$, we have the probability of a collision using b bits with m messages (sequences) is:

$$P(b, m) = m^2/2^{b+1}$$

Note that the collision probability depends on the number of messages, but not their size.

Solving for the minimum number of bits b as a function of an expected number of sequences m and a desired tolerance for collisions of P :

$$b(m, P) = \log_2 \left(\frac{m^2}{P} \right) - 1$$

This equation is derived from equations that assume that $m \ll s$, where $s = 2^b$. When computing $b(m, P)$, we'll require that $m/s \leq 10^{-3}$ as follows:

$$m/s \leq 10^{-3}$$

is approximately equivalent to:

$$m/2^b \leq 2^{-5}$$

$$m \leq 2^{b-5}$$

$$\log_2 m \leq b - 5$$

$$b \geq 5 + \log_2 m$$

For completeness:

Solving for the number of messages:

$$m(b, P) = \sqrt{P * 2^{b+1}}$$

This equation is not used further in this analysis.

```
def b2B3(b) :
    """Convert bits b to Bytes, rounded up modulo 3

    We report modulo 3 because the intent will be to use Base64 encoding, which is
    most efficient when inputs have a byte length modulo 3. (Otherwise, the resulting
    string is padded with characters that provide no information.)

    """
    return math.ceil(b/8/3) * 3
```

(continues on next page)

(continued from previous page)

```
def B(P, m):
    """return the number of bits needed to achieve a collision probability
    P for m messages

    Assumes m << 2^b.

    """
    b = math.log2(m**2 / P) - 1
    if b < 5 + math.log2(m):
        return "-"
    return b2B3(b)
```

```

6.9 Glossary

computed identifier An identifier that is *generated* from the object's data. Multiple groups who generated *computed identifiers* the same way will generate the same identifier for the same underlying data.

digest, ga4gh_digest A digest is a digital fingerprint of a block of binary data. A digest is always the same size, regardless of the size of the input data. It is statistically extremely unlikely for two fingerprints to match when the underlying data are distinct.

serialization The process of converting an object in memory into a stream of bytes that may be sent via the network, saved in a database, or written to a file.
